A listing of all subjects with clinically significant laboratory values is recommended to determine the pattern and clinical relevance of the laboratory change and to provide insight as to whether the change may be due to the investigational product. To illustrate, Table 4 provides three different patterns of clinically significant platelet values. Example A indicates a clinically significant low platelet count at baseline, which indicates a preexisting condition with no clinically relevant change observed during the study suggesting there was no adverse product effect on this variable. Example B shows a normal, baseline platelet value. With each subsequent treatment visit, a successive decrease in platelet count is seen with the value at the final treatment visit exceeding the threshold for a clinically significant low platelet count. The posttreatment value shows the platelet count, although still below normal limits, is improving and approaching normal. Such a pattern as shown in this example would be highly suggestive that the change in the platelet count was due to the investigational product unless there was a plausible alternative explanation, i.e., the patient started taking a concomitant medication known to be toxic to platelets. A spurious abnormally low platelet count is suggested in Example C. By these examples one can see the importance of evaluating listings for all subjects with clinically significant laboratory values. Such listings should include the study protocol/study site number, subject number, the subject's age and gender, and all values obtained throughout the study for that subject for that particular laboratory analyte, including the baseline, treatment, and any posttreatment values (if available). Each

visit should also include the date each value was obtained and the number of days relative to baseline that the value was obtained. All abnormal values should be appropriately flagged as low (L), high (H), and clinically significant (CS).

Laboratory-Related Adverse Events

To ensure a comprehensive review of laboratory data it is also important to examine the incidence of laboratory-related adverse events to determine if there are similar findings found in other laboratory analyses. For instance, if the incidence of the adverse event “hypokalemia” (low potassium) is either statistically or clinically significantly greater in the investigational product group compared to placebo, it is important to determine if similar trends were seen in the other laboratory analyses performed. Such trends might include a mean decrease in potassium, a higher percentage of subjects in the investigational product group with decreased shifts in potassium compared to placebo, or a higher percentage of subjects with clinically significantly low potassium values observed in the investigational group compared to placebo. Further clinical weight is given for those laboratory-related adverse events that were considered to be related to treatment and were serious^[9] and/or resulted in discontinuation from treatment.

SCIENTIFIC ISSUES

The results of any laboratory analysis is dependent on the correctness of the laboratory data analyzed, understanding the limitations of the laboratory analysis employed, and determining the clinical relevance of the findings. Factors affecting the poolability, i.e., integration of data across investigative sites and across studies must also be considered. These issues are discussed next.

Table 3 Summary of Subjects with Clinically Significant Shifts from Baseline

	Dose 1 (n = 50)	Dose 2 (n = 50)	All doses (n = 100)	Placebo (n = 50)
AST $\geq 3 \times$ Upper limit of reference range (10–40 U/L) Number (%)	3 (6%)	10 (20%)	13 (13%)	4 (8%)
ALT $\geq 3 \times$ Upper limit of reference range (5–35 U/L) Number (%)	2 (4%)	13 (26%)	15 (15%)	3 (6%)

Table 4 Examples of Clinically Significant Values that Suggest Different Etiologies

Visit	Example A ($\times 10^3/\text{mm}^3$)	Example B ($\times 10^3/\text{mm}^3$)	Example C ($\times 10^3/\text{mm}^3$)
Baseline	70 (L, CS)	175	175
Treatment week 4	110 (L)	150	150
Treatment week 8	65 (L, CS)	100 (L)	55 (L, CS) Repeat = 155
Treatment week 12 (final visit)	75 (L, CS)	70 (L, CS)	160
Follow-up visit (posttreatment)	None	140 (L)	165

L = below lower limit of reference range [(150–350) $\times 10^3/\text{mm}^3$]; CS = clinically significant.

Laboratory Measurement Errors

It is important to be aware of potential errors that may occur in obtaining laboratory values. Such errors may occur in the collection, processing, transporting, and storage of samples. These include the time of day the sample was obtained (e.g., adrenal hormone production is affected by circadian rhythms); whether the specimen was a fasting or nonfasting sample (relevant for glucose and lipid determinations); venipuncture technique; whether the proper collection tube was used; whether the sample tube was labeled with the correct subject's name; and how the specimen was transported and stored. Other factors include the precision and accuracy of the method used to analyze the sample and whether the sample was measured manually or automatically.^[2] Correct calculation, transcription, data entry, and data conversion are also important factors in assuring accurate laboratory values.

Data-Conversion Issues

When obtaining laboratory values it is important to understand that laboratory reference ranges may change during the course of a clinical trial. This must be taken into account when the data are analyzed because this will impact the determination of normal and abnormal values and may change the numerical threshold for clinically significant values. For instance the Neuropharmacology Division of the FDA defines ALT values ≥ 3 times the upper limit of normal as clinically significant.^[6] If the ALT reference range was initially determined to be 5–40 IU, values above 40 IU would be considered to be abnormally high, and a value of 125 IU would be clinically significant. However, if the reference range changed to 5–45 IU, a value of 42 IU would be normal and a value of 125 IU would no longer be categorized as clinically significantly abnormal. Differences in laboratory reference ranges must also be considered in multicenter studies where each site may be using its own local laboratory. When doing multinational studies, the laboratory units to be used for analysis must be determined, i.e., conventional or SI units. Unit conversion using predefined algorithms must then take place.^[10] Errors in data conversion are not uncommon.

Data-Integration Issues

Pooling of laboratory data across investigative sites is required in multicenter and multinational studies. Furthermore, for product registration proposes, pooling of studies is often required to adequately show the safety profile of the investigational product under review because individual studies may not be large enough to identify important safety trends. Considerations in pooling studies include the following: study design, i.e., double-blind placebo-controlled studies vs. comparator-controlled studies vs. open-label studies; dose of investigational product and

active-controlled agent; number of randomized patients; and the duration of the study. Clearly, pooling large, Phase 3, placebo-controlled studies with similar study durations utilizing similar doses would provide more meaningful information than pooling small, open-label, dose-ranging studies where investigational product was given for short periods of time. Such factors must be taken into account when data are pooled.

Subgroup Analyses

Potential interactions other than the effect of the investigational product on a laboratory parameter should also be explored if there is sufficient data to do so. Subgroup analyses are therefore usually performed in large studies or on pooled data. Common variables for subgroup analyses typically include gender, age, and race. Other variables to be analyzed may be dependent on the pharmacological properties of the product. For example, if there is a suspicion that renal function may influence laboratory changes, a subgroup analysis comparing patients with normal baseline renal function should be compared to patients with abnormal baseline renal function. The information from subgroup analyses is limited and confounding when the subgroups are skewed, e.g., there are considerably more younger patients (≤ 65 years old) than older patients.

Other Analysis Issues

A decision needs to be made regarding what time points should be used for each analysis, i.e., baseline to each visit, baseline to final treatment, or some combination of the two. For shorter-term studies, baseline to final treatment may be adequate. In longer-term studies, looking at mean changes over time is often performed to determine if time may be a factor in any observed changes from baseline. These conventions are often applied to the shift table analysis as well. For shift tables, the lowest and highest postbaseline values regardless of when these occurred might also be considered. Because of the clinical relevance of clinically significant laboratory values, it is recommended that a subject be included in the clinically significant categorical analysis if the subject has one or more values that exceed the predefined threshold regardless of when the observation was made postbaseline. The recommended listing of clinically significant values discussed in the “Methods” section allows the reviewer to determine the time course and pattern of the observed clinically significant value.

Central Laboratories

The use of central laboratories, when available, makes data integration easier and reduces errors in transcription, unit conversion, and reporting inconsistencies. Laboratory samples are typically delivered to a central processing center where the same methodological standards are used.

Reference ranges are established for each analyte. Values below or above the reference range are flagged as such. Furthermore, “panic” values, which are clinically significant and of clinical concern, can be established so that the investigator and sponsor are promptly notified of such values to ensure the proper care of the patient.

Printouts of laboratory results are usually used in place of a separate laboratory case report form. This not only reduces transcription time but also reduces human error in transcribing results. Data tapes are often made available to the sponsor so no additional data entry of the laboratory results is required.

Offsetting the benefits of using a central laboratory are the costs, changes in reference values that occur even with the use of central laboratories especially during trials of longer duration. Furthermore, not all sites participating in a multinational study are likely to be able to use one central laboratory because timely shipment of samples across country borders or overseas is not practical. Even with these limitations the use of central laboratories when available is still preferred.

Study Population Considerations

In interpreting the clinical significance of laboratory changes, it is also important to understand the characteristics of the study population with respect to their underlying diseases and the concomitant medications they are taking. For instance, if a study is being conducted in patients with severe heart failure, it is likely that this study population will be taking diuretics. Diuretic use can affect a number of laboratory parameters including sodium, potassium, calcium, uric acid, and glucose levels.^[11] In such cases, if there is an observed change in one or more of these analytes it has to be determined if the change is due to the investigational product, the underlying disease, or the concomitant medication. This determination can usually be made in comparative trials where there would be no difference in “background noise” between treatment groups assuming that the two treatment groups were balanced with respect to the severity and duration of heart failure, there were no significant differences in the presence of underlying disease or in concomitant use of diuretics, and there were no differences in baseline mean laboratory values. This becomes more of a challenge in open-label trials where there is no comparative group to determine the background noise of the study population.

Clinical Relevance of Laboratory Findings

There are a number of factors that must be taken into account in the proper interpretation of laboratory findings. These factors include spurious laboratory values, changes in some laboratory analytes that are directionally opposite to changes seen in other related analytes, statistically significant findings that are not clinically relevant, and clinically relevant findings that are not statistically significant.

Real Laboratory Findings Vs. Laboratory Error or Artifact

It is important to verify all clinically significantly abnormal laboratory values because some extreme values may simply be due to laboratory error or artifact. For instance, it is not uncommon to find elevated levels of potassium. Large increases in this electrolyte can result in death. Subjects with normal renal function are usually able to excrete excess potassium. Therefore, for any clinically significant elevated potassium value it is important to look at renal function as well. A significantly elevated potassium level in a healthy subject with a normal urinalysis and normal creatinine and BUN values would suggest a laboratory error or artifact. Red blood cells are rich sources of potassium. If a blood sample sits too long or if the red blood cells are damaged in some way, potassium can escape from the red blood cells and settle in the serum where it would increase the serum content of potassium and result in an abnormally high potassium value when measured. Sometimes a laboratory report will indicate that the blood sample was hemolyzed (i.e., the red blood cells were ruptured), and a repeat potassium level should be obtained. Therefore, all clinically significantly abnormal laboratory data should be critically reviewed and repeated, if necessary, before such data are included in any laboratory analysis.

Laboratory data must also be reviewed for the directional change of similar analytes. For example, hemoglobin and hematocrit are both measurements involving red blood cells (RBCs) and consequently should move in the same direction. A patient with anemia would be expected to have both a low hemoglobin value and a low hematocrit value. If the hematocrit was listed as below normal and hemoglobin was listed as above normal, one should suspect a laboratory error or transcription error for one of these analytes. Similarly, in analyzing hemoglobin and hematocrit mean changes, shift tables, and clinically significant changes, each analysis should show similar directions/patterns for these analytes. Therefore, if there was a mean increase for hematocrit but a decrease in mean hemoglobin this would either represent an analysis error, or if no analysis error was detected these disparate findings would suggest that such findings were not clinically meaningful.

Clinical Correlations

In the “Methods” section four different approaches to analyzing laboratory data were summarized. It would not be unusual if all four analyses did not reveal similar trends for any given analyte; however, the more analyses that show similar trends the greater clinical weight there is that the finding is clinically meaningful. Using the example of hemoglobin and hematocrit discussed above, if the mean change analysis indicated that both hemoglobin and hematocrit showed statistically significant decreases from baseline, the other analyses should

Table 5 In-Text Laboratory Analysis Display

Analyte X	Dose 1 (n = 50)	Dose 2 (n = 50)	All doses (n = 100)	Placebo (n = 50)	Comparator (n = 50)
Mean change from baseline to endpoint $\pm$ SD	10.8 $\pm$ 0.3	9.7 $\pm$ 0.8	10.3 $\pm$ 0.5	9.5 $\pm$ 1.2	11.6 $\pm$ 0.2
No. (%) low/normal to high	1 (2%)	2 (4%)	3 (3%)	1 (2%)	5 (10%)
No. (%) high/normal to low	0	1 (2%)	1 (1%)	0	1 (2%)
No. (%) clinically significant changes	0	1 (2%)	1 (1%)	0	2 (4%)

be reviewed for similar trends. If this was a clinically relevant finding one might see a greater percentage of patients with decreases than increases in these analytes in the shift tables. There may also be a higher proportion of subjects with clinically significantly low values. A review of adverse events might show a higher incidence of anemia in the group that received the investigational drug. All these findings would lend weight to the observation that decreases in hemoglobin and hematocrit values were “real” findings.

Table 5 shows a summary of the findings of different laboratory analyses for any given analyte. Such data display help in the review of laboratory findings and in determining the clinical relevance of the laboratory findings.

Clinical Significance vs. Statistical Significance

Statistical analysis of laboratory data for safety determination provides an important tool in aiding the objective interpretation of laboratory findings. Its use is analogous to a filter that blocks out extraneous “random noise” and allows the reviewer to focus on the data that require more in-depth review, helping to identify and quantify any relevant safety findings. However, statistical testing is not always indicated in the analysis of laboratory data.

For instance, a drug that showed frequent toxic effects on the bone marrow would have an unfavorable benefit to risk ratio unless the drug was a chemotherapeutic agent for the treatment of a serious and life-threatening disease such as cancer. Therefore, it would be unexpected and unacceptable to see statistically significant mean decreases in RBCs, WBCs, and platelet counts routinely in a patient population taking drugs for self-limiting conditions such as the common cold. Nevertheless, a small number of individuals, due to hypersensitivity and idiosyncratic reactions, could still be at risk. In one population case control study the incidence of drug-induced aplastic anemia (a serious condition that affects the bone marrow and can lead to severe anemia, life-threatening infections, and bleeding episodes) was quite rare, i.e., estimated to be 0.5 per million per year.^[12] Because these events occur so rarely, mean changes and routine shift tables would unlikely identify any problem. However, if a patient demonstrated the platelet pattern shown in Example B (Table 4) and no alternative explanation could

be found, this single patient's findings would be sufficient to raise suspicion that the biopharmaceutical product under investigation may cause clinically relevant decreases in platelets. The clinical investigation team would then need to be on “heightened alert” for similar cases.

CONCLUSION

In summary, accurate laboratory data, appropriate analysis, and clinical correlation are requisite to ensure the validity of laboratory findings. Having assured this, laboratory analyses play an invaluable role in helping define the safety profile of biopharmaceutical products under investigation.

ACKNOWLEDGMENT

I would like to thank Dr. Carmela Skillman for her critical review of the manuscript and her invaluable assistance in its preparation.

Abstract

A variable is latent if it cannot be directly measured, but can be inferred through the measurement of other related observable variables. In this entry, different models and methods of latent class analysis are examined, and practical applications and examples are provided.

Keywords: Latent class model; Latent variable; Markov chain Monte Carlo; Major depression; Sensitivity; Validity.

INTRODUCTION

A variable is latent if it cannot be directly measured, but can be inferred through the measurement of other related observable variables. For example, in mental health research, major depression is a latent variable: one cannot directly measure depression, but we can observe symptoms of depression, such as sadness, weight loss, and fatigue. Latent variables can take different forms. They can be continuous, such as intelligence quotient (IQ), or they can be categorical, such as social class. In biomedical research, conceptualizing latent outcome variables as categorical is appealing because the categories can be thought of as diagnostic classes.

The latent class model (LCM) is a method for defining a categorical latent variable based on a set of discrete observed variables. It views the population as a set of subpopulations (or classes) and the observed variables as surrogates that imperfectly measure to which class an individual belongs.^[1] A more mathematical interpretation of the LCM is that it describes the association of the observed variables in a multiway contingency table. In the case of K observed binary variables, the dimension of the contingency table is 2^K . For example, we can fit a LCM using a set of symptoms of depression where symptoms are recorded as “present” or “absent,” and our latent class variable is depression. There are other models for related latent variable situations: for a categorical latent variable and continuous observed variables, we use the latent profile model; for a continuous latent variable and continuous observed variables, we use factor analysis; and for a continuous latent variable and categorical observed variables, we use latent trait models.

Many situations in which a disorder is diagnosed as a syndrome (i.e., a constellation of symptoms) are appropriate

applications for a latent class analysis. However, it is most useful when the observed variables measure diagnoses, rather than continuous scores, and the patterns of the symptoms are thought to contain more information than simply summing up the number of symptoms. The goal of the LCM is to cluster individuals into diagnostic groups, as opposed to grouping the observed symptoms (as in factor analysis).

The clinical utility of the LCM is multifold. Individuals can be clinically diagnosed into latent disease categories. This identification can help allocate resources appropriately and efficiently. The LCM can describe the prevalence of a disease or disorder, facilitating a better understanding of the resources necessary in the community and the potential benefits of early interventions in some instances. Additionally, the LCM can predict prevalence of disease in different populations, which can help in estimation and allocation of services. The LCM has also been used for validation of diagnostic criteria.

A MENTAL HEALTH EXAMPLE: MAJOR DEPRESSION IN THE EPIDEMIOLOGIC CATCHMENT AREA STUDY

Latent class models are prevalent in many areas of medical research, especially in mental health and psychiatric research. For example, LCMs have been used for defining and understanding autism,^[2,3] attention-deficit hyperactivity disorder (ADHD),^[4] alcoholism,^[5,6] bulimia,^[7] depression,^[8–13] harmful behaviors,^[14] Alzheimer’s disease,^[15] schizophrenia,^[16] anxiety and depression in children,^[17] and general psychoses and syndromes,^[18,19] among others. Outside of mental health, LCMs have

been seen in medical research areas such as gerontology,^[20] genetics,^[21] medical care,^[22,23] ophthalmology,^[24] fatigue,^[25,26] and cytometry.^[27] The origin of the LCM in psychiatric research was the validation by Young^[28] of the classification system for schizophrenia developed by Taylor and Abrams.^[29] Since then, the LCM has been used by many researchers for evaluating criterion validity of diagnostic definitions.^[4,9,30,31]

Major depression is a classic example of a latent variable. Moreover, it has been studied and analyzed via LCMs by many researchers.^[9–13,17,30,31] The results of these studies vary largely because of differences in population composition: some are patient populations, while others are epidemiologic samples. The Epidemiologic Catchment Area Study (ECA), which is a multisite, multiwave community sample of individuals, was used in four of these publications,^[9–12] and it will be used here to facilitate discussion of the LCM in practice.

The ECA includes a series of surveys conducted by university-based researchers in five community populations focusing on mental health.^[32] Baseline assessments were made in 1981 (wave 1) in 13,538 respondents using the Diagnostic Interview Schedule (DIS)^[33] and again in 1982 (wave 2). The Baltimore site, which interviewed 3481 individuals in wave 1, followed up its sample between 1993 and 1996 and was able to conduct wave 3 DIS interviews of 1865 of the original 3481 from its 1981 community dwelling cohort. Of the original 3481, 452 could not be located, 878 has died, and 286 did not agree to participate. Validity of the DIS is shown in Ref. [34].

For each symptom in the DIS, individuals were asked if they had ever experienced the symptom. If the respondent answered yes, a series of probe questions followed which assured that the symptom was not trivial. Nontrivial symptoms with no medical explanation are considered plausible psychiatric symptoms, and for these, the respondent was asked to date the most recent occurrence of the symptom. The 25 questions relating to depression in the DIS can be collapsed into 10 symptom groups for depression as defined by the International Classification of Diseases, edition 10 (ICD-10)^[35] and the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV).^[36] For example, all questions in the DIS relating to sleeping problems define one of the symptom groups. Reporting at least one of the sleeping symptoms (i.e., trouble falling asleep, trouble waking, or sleeping too much) is considered a positive symptom response for that symptom group.

The 10 symptom groups and the prevalence of symptoms in the ECA Baltimore site in wave 3 (1993–1996) are in Table 1. The most prevalent symptom group is group 5 (sleeping problems) and the least prevalent is group 6 (guilty/sinful feelings). These 10 symptom groups will be the observed variables that we use to define the latent variable depression in our LCM.

Table 1 Prevalence in Symptom Groups in ECA Wave 3 Depression Data, $N = 1322$

Group	Symptoms	Prevalence
1	Depressed mood Disinterest in sex	0.06
2	Less fun Loss of enjoyment	0.08
3	Reduced energy/fatigued Ideas of self-harm	0.05
4	Want to die Suicidal thoughts Suicide attempts Trouble falling asleep	0.05
5	Trouble waking Sleep too much	0.09
6	Guilty/sinful feelings Reduced concentration	0.02
7	Slow thoughts Indecisive	0.04
8	Feel inferior Lacking self-confidence Loss of appetite	0.03
9	Weight loss Increased appetite Weight gain Slow movement	0.08
10	Fast movement Fidgety	0.04

THE LATENT CLASS MODEL

The LCM provides us with two types of parameters which define the model—(i) class size: a vector indicating the proportion of individuals in each of the classes; and (ii) symptom prevalences: for each class, we obtain a vector of probabilities indicating the prevalence of each of the symptoms in the class.

Notation

In the LCM, the observed variables are often called items, symptoms, or indicators. To specify a LCM with M classes and K observed symptoms, we define Y_i to be a vector of length K corresponding to the K (binary) symptoms of individual i , with 1 indicating presence of symptom and 0 indicating absence. The key model parameters are p and π . p is a K by M matrix of the symptom prevalences by class. Specifically, p_{km} is the probability that an individual in class m will exhibit or report symptom k . The parameter vector π has length M and represents the class sizes. For example, π_m is the proportion of individuals in the population in class m . For a dataset with N individuals, the latent

Table 2 Parameter Estimates in a Three-Class Latent Class Model for Depression

		Class 1	Class 2	Class 3
1	Depressed mood	0.02	0.30	0.78
2	Loss of interest	0.02	0.32	0.91
3	Fatigue	0.01	0.25	0.64
4	Morbid thoughts	0.02	0.24	0.54
5	Sleep	0.03	0.49	0.77
6	Guilt/sin	< 0.01	0.08	0.37
7	Concentration	0.01	0.15	0.78
8	Self-esteem	< 0.01	0.10	0.56
9	Appetite/weight	0.04	0.31	0.78
10	Movement	0.01	0.17	0.73
	Class size	0.88	0.09	0.03

class variable is denoted by the N -vector η , where η_i is subject i 's latent class and can take integer values between 1 and M .

Table 2 provides the parameter estimates of the three-class latent class model for depression. The class size vector π is (0.88, 0.09, 0.03). Class 1 appears to have low prevalence of symptom, with all less than 0.05. Class 3 has the highest prevalences for all symptoms, with a range of 0.37 for guilt/sinful feelings to 0.91 for loss of interest. The prevalences in class 2 range from 0.08–0.49, with most in the 0.15–0.40 range. Based on these results, we can conclude that, assuming that three classes of depression exist, there is a large class of non-depressed individuals (88%) in the population, a small class of depressed individuals (3%), and a class of individuals reporting a few symptoms, but not appearing to be severely depressed (9%).

The Likelihood Function

Now that the model parameters are better understood, it is important to consider the likelihood function of the LCM. The probability that individual i reports a specific symptom pattern y^* can be written as follows:

$$P(Y_i = y^* | p, \pi) = \sum_{m=1}^M \pi_m \prod_{k=1}^K p_{km}^{y_{ik}^*} (1 - p_{km})^{(1-y_{ik}^*)} \quad (1)$$

This is essentially a weighted average of the probability of reporting the pattern in each of the classes where the weights are the class sizes. Using Eq. 1, we can write down the likelihood function for the latent class model by taking the product over N :

$$L(p, \pi | Y) = \prod_{i=1}^N \sum_{m=1}^M \pi_m \prod_{k=1}^K p_{km}^{y_{ik}} (1 - p_{km})^{(1-y_{ik})} \quad (2)$$

where Y is the $N \times K$ data matrix for data on the N individuals and the K observed variables.

Notice that nowhere in the likelihood do we see the latent class variable η . Although it is not a parameter that is estimated via the likelihood function, it does play a role in estimation when using Bayesian estimation approaches where we condition on η . Eq. 3 shows the conditional distribution of the data, given η and the other model parameters.

$$f(Y | \eta, p) = \prod_{i=1}^N \prod_{k=1}^K p_{\eta k}^{y_{ik}} (1 - p_{\eta k})^{(1-y_{ik})} \quad (3)$$

Latent Class Model Assumptions

The LCM has several assumptions. The first, a rather simple assumption, is that each individual belongs to one and only one of the M classes. Second, the number of classes M must be chosen a priori to fit the model. It is most common that one does not know the number of classes, and in that case, you would iteratively fit two-class, three-class, etc. models until you find one that is suitable based on goodness of fit and/or comparison of models. The last assumption to mention is conditional independence: conditional on an individual's latent class, the individual's responses to items are independent. Mathematically,

$$P(Y_{ik}, Y_{ij} | \eta_i) = P(Y_{ik} | \eta_i) P(Y_{ij} | \eta_i) \quad (4)$$

This assumption is obvious from the likelihood: the product over the K symptoms implies that the occurrence of those symptoms is independent, conditional on the class. While the first two assumptions are implicit, the conditional independence assumption is sometimes violated, leading to incorrect inferences. As such, it is an important assumption to check after fitting the LCM. This will be discussed in "Model Evaluation."

The above noted are statistical assumptions. There are some other practical assumptions about the validity of the latent class model worth discussing. Just as in factor analysis and other multivariate techniques, the items that you choose to include in the model are assumed to "define" the underlying construct. For our example of depression, by including exactly these 10 symptom groups, we are assuming that exactly these 10 symptom groups define depression and that we have not neglected to include any other relevant symptoms from the model.

Identifiability

The identifiability of a particular parameter describes the ability of the data to uniquely estimate (or identify) the model parameter. Of the several types of identifiability described in the statistics literature, two types of identifiability are particularly relevant for latent class models: local identifiability and weak identifiability.

Local Identifiability

Recall that a latent class model is a method to describe a multiway contingency table. Given that there are 2^K cells in this contingency table (for binary items), it is not possible to identify a model that has more than 2^K parameters. For this reason, a necessary condition for identifiability of LCMs is $M(K-1) < 2^K$. However, this is not a sufficient condition—there are some models satisfying this inequality that are not identifiable. Goodman^[37] introduced a sufficient condition for identifiability: $M < 2^{(K-1)/2}$. Models satisfying the necessary but not the sufficient condition may or may not be identifiable. Note that this kind of identifiability is what can be called “theoretical” or “asymptotic” identifiability because it is based on the assumption that the dataset is large enough to identify all model parameters. However, LCMs often require very large datasets to be able to estimate all parameters with relative precision.

The notion of satisfying the local identifiability conditions, yet having too small a dataset to identify all model parameters, can be called “empirical identifiability.” Via statistical theory, empirical identifiability is equivalent to having a nonsingular information matrix. In practice, one can calculate the rank of the Jacobian. However, it is often more practical to estimate the model of interest using several starting values in the estimation procedure, as described in the next section. If different starting values lead to different solutions, then empirical identifiability may not have been achieved.

Weak Identifiability

Recall that the Bayesian statistical paradigm is based on the idea that a statistical model is composed of two key quantities: the prior distribution and the likelihood. These are combined in a Bayesian analysis to produce the posterior distribution of the parameters, with which we make statistical inferences. In Bayesian estimation procedures, “weak identifiability” describes the information for parameter estimation provided in the prior distribution and the likelihood: if the prior distribution provides most of the information and the data provide relatively little, then we say that the particular parameter is only weakly identified. This is a slightly different concept than local identifiability in its traditional interpretation. Weak identifiability is defined in the context of Bayesian statistics and occurs when the technical conditions for “theoretical” identifiability (as

mentioned above) are met, but the data provide little information about some parameters so that their posterior and prior distributions are very similar. Weak identifiability also implies that empirical identifiability, as defined in the previous section, is not achieved. Lindley^[38] notes that although a Bayesian model may be only weakly identified, it can still be valid in the sense that the model can still adequately describe the data via its identifiable parameters. It is, however, important to determine which parameters, or functions of parameters, are identifiable and only interpret the model results based on these parameters.

Note that there is a significant difference between the local identifiability discussed above and weak identifiability. Both concepts describe the ability of the data to estimate the parameters, but if we have nonidentifiability in the case where we are estimating the model using a non-Bayesian approach, we cannot estimate the parameters. However, if we choose a Bayesian approach (as described in “Estimation Methods”), we can rely on prior distributions to estimate parameters. But, as noted above, this does not mean that the weakly identified parameters can be interpreted: it simply means that the model is still valid and the identifiable parameters can be interpreted. Moreover, in the case where there is a priori information about the latent classes, either from previous analyses or based on expert opinion, this information can be included in a stronger prior distribution for a parameter. For example, in our depression example, it is well known that the majority of the general population does not suffer from depression. We could use this to assist in modeling the π vector via the prior distribution for π . However, using strong priors should only be carried out when there is good evidence with which to do so.

Sample Size Considerations

One potential limitation of the LCM is that it usually requires a large sample size for model estimation, usually at least several hundred observations and, in some cases, several thousand observations. The size of the dataset required depends essentially on the size of the classes and on the variability of the items in the sample. For example, for evaluating depression, we have an epidemiologic sample which, as expected, has relatively low prevalence of symptoms, so that there is relatively little variability in the symptoms in the sample. Additionally, depression is relatively rare in an epidemiologic setting, and so we have one large class, and then we expect one or more rather small classes. Because of these two characteristics, we need a relatively large sample to detect the depressed classes in our population. If we instead had a patient population in which symptoms were more prevalent (i.e., prevalence for symptoms closer to 0.50) and the “nondepressed” individuals did not account for the large majority of the sample, then we would be able to detect smaller classes with a smaller sample.

A Monte Carlo study, in which many samples are drawn from a hypothesized population with user-specified parameter values, can be conducted. The model is then estimated for each sample, and parameter estimated and standard errors are averaged across the samples. Statistical power for a particular scenario and sample size can then be estimated as the percentage of samples in which the null hypothesis was rejected.^[39]

Posterior Probability of Class Membership

A useful quantity that can be estimated from the model parameters is the posterior probability of membership. This provides, for each possible response pattern, the probability that an individual with the response pattern y^* belongs to each of the classes:

$$P(\eta_i = m | y^*) = \frac{\pi_m \left(\prod_{k=1}^K p_{km}^{y_k^*} (1 - p_{km})^{(1-y_k^*)} \right)}{\prod_{l=1}^M \pi_l \left(\prod_{k=1}^K p_{kl}^{y_k^*} (1 - p_{kl})^{(1-y_k^*)} \right)} \quad (5)$$

Although it may seem complex at first glance, it is a simple implementation of Bayes rule on Eq. 2. For example, using the information provided in Table 2, we can estimate the likely class for an individual reporting only “loss of interest” and “sleep” symptoms. To do this, we use the equation above. For this reported pattern, we find that the individual has a 17% chance of being in class 1, an 83% chance of being in class 2, and less than a 1% chance of being in class 3. For other more common patterns, see Table 3.

A Reparameterization

In some settings, it proves useful to reparameterize the LCM using parameters on the logit scale:

$$p_{km} = \frac{e^{\gamma_{km}}}{1 + e^{\gamma_{km}}}$$

$$\pi_m = \frac{e^{\alpha_m}}{\sum_{m=1}^M e^{\alpha_m}}$$

When using the parameterization above with parameters γ and α , the likelihood function becomes:

$$L(p, \pi | y) = \prod_{i=1}^N \sum_{m=1}^M \frac{e^{\alpha_m}}{\sum_{l=1}^M e^{\alpha_l}} \prod_{k=1}^K \frac{e^{\gamma_{km} y_{ik}}}{1 + e^{\gamma_{km}}} \quad (6)$$

where $\alpha_M = 0$.

For example, in the Mplus software program,^[40] which implements an EM algorithm for model estimation, and in some Bayesian approaches, this reparameterization is used (see Ref. [10] and “Estimation Methods” for more details).

ESTIMATION METHODS

Likelihood-Based Approaches

The most prevalent estimation method for the LCM is a likelihood-based approach. Specifically, expectation-maximization (EM) algorithms are most often used. There are numerous software packages designed to estimate latent class models using this approach: Mplus,^[40] Latent-GOLD, “maximum likelihood latent structure analysis” (MLLSA), “linear structural regression” (LISREL), and others. For a rather comprehensive list of software, suggestions, and links to software, see Ref. [41]. Note that many of these software packages either suggest or require the user to supply “starting values” for the parameters.

A major consideration when using likelihood-based approaches is the potential problem of lack of convergence. This may occur when there are identifiability problems (that is, the dataset is relatively small, or one of the class sizes is very small and there are not enough individuals in this small class to estimate parameters with reasonable precision), or the conditional independence assumption has been violated. It is often suggested that whenever fitting a LCM, one should repeat the estimation procedure several times using different sets of starting values. This will often (but not always) diagnose a problematic model fit.

Another reason that lack of convergence arises is that the parameter estimates may get “stuck” at the boundary of the parameter space during estimation. This is a result of the algorithmic nature of the fitting procedure. In this case, the resulting model fit will show parameter estimates

Table 3 Posterior Probabilities of Class Membership for Common Response Patterns

	Pattern	Class 1	Class 2	Class 3
No symptoms	0000000000	0.99	0.01	< 0.01
All symptoms	1111111111	< 0.01	< 0.01	> 0.99
Somatic symptoms	1101011100	0.01	0.97	0.03
Mood symptoms	0010100011	< 0.01	0.06	0.94
Depressed mood only	1000000000	0.87	0.13	< 0.01

(usually in the p matrix) that have values of exactly 0 or 1. When you encounter estimates such as these, it is unlikely that these are correct. It is probable that the model did not properly converge and should be refit using different starting values.

Markov Chain Monte Carlo Estimation Approaches

The Markov chain Monte Carlo (MCMC) approach to model estimation stems from Bayesian methodology. The general idea is described by Casella and George,^[42] and a more technical treatment can be found in Geman and Geman.^[43] There are many examples of models akin to latent class models which are estimated by MCMC.^[44–48] To see details of the MCMC approach for LCMs, see Ref. [10]. This model fitting approach tends to require more user input and statistical expertise than the likelihood-based approaches. So while there are arguably benefits to the use of the MCMC approach, it is not necessarily a feasible estimation method for those unfamiliar with Bayesian statistics. The MCMC estimation can be performed using the Bayesian package WinBUGS or can be programmed in mathematical or statistical software such as C, Fortran, SAS, Mathematica, Splus, or R.

A difference between the MCMC and the likelihood-based approach is that the likelihood-based software packages usually provide point estimates and standard errors of model parameters (i.e., π and p , or in the parameterized case, α and γ). From these, the user can estimate posterior probabilities of class membership (see “Latent Class Model Assumptions”) but not their standard errors. From the MCMC estimation procedure, the user obtains point estimates and precision estimates of the p and π parameters and has the additional benefit of obtaining point estimates and precision for any function of the parameters. This is a nice feature of the MCMC approach, especially when the goals of the analysis are more than just to obtain the standard model parameters. For example, in “Practical Application,” we use the results from the MCMC to derive sensitivity and specificity estimates (and estimates of their precision) using the MCMC results. This could not be performed using standard likelihood-based software.

In the MCMC approach, the user does not need to specify parameter starting values. However, he does need to choose prior distributions for each parameter. These distributions can be “vague,” essentially providing no a priori information about the parameter estimates, or they can be informative. In some cases, it is preferable to use informative priors. One advantage of the use of priors is that we can avoid the parameter boundary problem that the likelihood-based approach encounters: we can choose priors that do not allow parameters to take values on the parameter boundary.

There are some shortcomings to the MCMC approach. It tends to take longer than the likelihood-based approach

(although this is not universally true and, in many cases, both converge rather quickly depending on the size of the dataset). Additionally, in some cases, the post hoc calculations required to get to the parameters of interest can be substantial and require some programming expertise.

MODEL EVALUATION

Choosing a Model and Assessing Fit

There has been considerable debate about approaches for model selection and for assessing goodness of fit in latent class models. Historically, the most popular approach has been to use likelihood ratio tests or Pearson chi-square statistics to assess fit or choose models. This assumption is not necessarily valid in most cases for a variety of reasons.^[49–52] Some of these reasons include that these statistics do not generally follow a χ^2 distribution in the LCM case, and that a k -class model is not necessarily nested in a $k + 1$ -class model. Additionally, Collins et al.^[50] have shown that these statistics may be either too liberal or too conservative, depending on factors including sample size, number of items, and number of classes. Information criteria, notably the Akaike Information Criteria (AIC)^[53] and the Bayesian Information Criteria (BIC),^[54] are alternative model selection statistics. The BIC is particularly appropriate for LCMs because of its adjustment for sample size, which tends to be large for most latent class analyses. The asymptotic properties of these two information criteria are such that the AIC is not consistent but is efficient for large sample sizes, while the BIC is consistent and not efficient.^[55,56] In simulation studies, the BIC typically outperforms AIC, with the AIC often supporting estimation of a larger number of classes than the BIC.^[57] The parametric bootstrap approach (BLRT) has been found to be a useful alternative to some of the problems arising in the statistics described above. Essentially, this method empirically determines the distributions of test statistics of interest (i.e., the likelihood ratio and the Pearson chi-square). This is described by Ref. [58] and can be seen in practice in Refs. [50,59]. In simulation studies, the BLRT typically outperforms the BIC, though it adds significantly to computation time.^[57]

Lo et al.^[60] have described an approximation to the distribution of the difference in likelihood values between a k -class model and a $k + 1$ -class model (LMR). In simulation studies, the LMR typically performs well, but not as well as the BLRT. Both the BLRT and the information criteria depend on model and distributional assumptions, whereas the LMR does not Ref. [57,60]. Therefore, in cases in which there is concern that the model is misspecified, the LMR might be preferable. It should be noted that Jeffries^[61] has pointed to a potential flaw in the proof supporting the LMR, though its impact (if any) on the utility of the statistic is not known. Graphical techniques for assessing model fit and for model selection have been introduced.^[10]

The Bayes factor, which has a close connection with the BIC,^[62] can be used in slightly different forms.^[63,65] Other methods including parsimony indices and ratios have been reviewed.^[66] Some additional approaches are the goodness-of-fit test^[67] and the Rudas-Clogg-Lindsey index.^[68]

As much as statistical appropriateness is an important consideration of model selection and/or model fit, another important factor in choosing the most appropriate model is the scientific interpretation. As stated in “Latent Class Model Assumptions,” there should be strong theory as a basis for choosing the items to include in the LCM. When choosing between models, one should consider how consistent each of the estimated sets of model parameters are with prior knowledge about the underlying latent variable of interest.

In our depression example, based on graphical techniques^[10] and the BIC, the three-class model was deemed to be the best model and demonstrated sufficient fit.

Assessing Model Assumptions

Recall the conditional independence assumption from “Latent Class Model Assumptions.” It is critical to assess whether or not this assumption has been met, otherwise incorrect inferences may be made. A relatively simple and straightforward approach is to assign individuals to classes based on their posterior probabilities of class membership and then determine whether or not items within classes of individuals appear to be independent. This can be performed in the binary item case by estimating odds ratios between items for individuals in the same class [for a total of $K \times M \times (M - 2)/2$ estimated odds ratios]. If these odds ratios appear to be close to 1, then the conditional independence assumption is met. However, if some of these odds ratios show evidence of being different than 1, then the model should be reconsidered. In cases where the vector of posterior probabilities of class membership does not clearly demonstrate membership in a particular class, simply assigning individuals to the model class may bias tests of model assumptions. Instead, one can multiply impute class membership a number of times and combine the results of the imputations to look for evidence that any of the between-indicator odds ratio are different than one [Ref. 20].

Solutions to violations of the conditional independence assumption include combining items that are highly related into one symptom group and fitting a model with more classes. Precision estimates for these odds ratios can be obtained with either method of estimation discussed.^[10,20]

PRACTICAL APPLICATION

We continue with our example of depression in the ECA study and compare our latent class model results with those of the DSM-IV diagnosis^[36] of major depression.^[10] After

using the MCMC approach for model estimation, we use the results of our MCMC chains to calculate the posterior distributions of sensitivity and specificity and positive and negative predictive values of the DSM-IV criteria, assuming that the latent class model is the “gold-standard” measure of depression. While this assumption may be quite strong, the latent class definition is a relatively unbiased and empirically driven estimate of depression, while the DSM-IV criteria are more subjectively determined by a panel experts. Additionally, it is important to consider that for a disorder to be considered in the DSM-IV, it must be something that is either treatable or would benefit from treatment, and that DSM-IV depression only allows for two diagnostic classes: depressed and nondepressed.

In Fig. 1A, the sensitivity of the DSM-IV diagnosis is shown for each of the three latent classes. The circles represent the estimated sensitivity, and the vertical lines represent the lower 2.5th percentile and the 97.5th percentile of the posterior distribution. (This is analogous to a 95% confidence interval, but not equivalent because of the differences in the estimation procedures.) Recall that the definition of sensitivity is the probability of positive diagnosis given true disease. In our example, we estimate the sensitivity of a DSM-IV diagnosis of depression given each of the three depression classes as defined by the LCM. For example, as we would expect, the probability of DSM-IV diagnosis given class 1 is very low (< 0.01) and the probability of DSM-IV diagnosis given class 3 is quite high (0.90). For class 2, we also obtained a very low sensitivity (0.05). Note that the specificity and the sensitivity for a given class must sum to 1, so that the specificities of classes 1, 2, and 3 are >0.99 , 0.95, and 0.10, respectively. These results imply that the DSM-IV diagnosis of depression is consistent with our class 3 of depression, and that those individuals that we consider to belong to class 2 are rarely identified as depressed by the DSM-IV criteria (only 5% of the time). As a result, the DSM-IV diagnosis has high sensitivity for diagnosing our class 3 depression (0.90) and high specificity (0.05) for classes 1 and 2.

We also consider the PPV and NPV of the DSM-IV diagnosis in our population. In our example, PPV is the probability that an individual who is diagnosed as depressed is truly depressed, and NPV is the probability that an individual who is diagnosed as not depressed is truly not depressed. Recall that, unlike sensitivity and specificity, PPV and NPV are statistics that are population-specific: they depend critically on the prevalence of disease in the population of interest. Our dataset is an epidemiologic sample from the East Baltimore community, and so our results will vary dramatically from a patient population where the prevalence of depression would be expected to be much higher. As above, we calculate the PPV and NPV for each class. For example, for PPV, we estimate the probability of being in each of the classes given a DSM-IV diagnosis. These quantities are shown in Fig. 1C and D. For classes 1, 2, and 3, we see that the PPVs are 0, 0.11, and 0.89, and the

Fig. 1 (A) Sensitivity, (B) specificity, (C) positive predictive value, and (D) negative predictive value of the DSM-IV diagnosis of depression as compared to the latent class model definition

NPVs are 0.91, 0.09, and 0, respectively. These numbers suggest that the PPV for class 3 and the NPV for class 1 are quite good in this population: for an individual who tests positive, the probability of that individual being in class 3 is 0.89, and for an individual who tests negative, the probability of that individual being in class 1 is 0.91. However, for class 2, we see less informative results: both PPV and NPV for class 2 are quite low, implying that individuals in class 2 are not well delineated by this test. Whether a class 2 individual's test result is positive or negative, that individual has about a 10% chance of being in class 2.

This approach is useful because it gives us a reference against which to compare diagnostic criteria. Critics may dislike the assumption that the latent class definition of depression is considered the “gold standard,” but without a true gold standard, the latent class definition can be argued to be our best empirically derived comparator.

CONCLUSION

The latent class model is a useful statistical tool for defining a latent categorical variable based on a set of observed categorical items. LCMs can be especially appropriate for identifying patterns of symptoms of disorders or diseases within populations, for summarizing the distribution of individuals within populations, for deriving diagnostic criteria, and for validation of diagnostic criteria developed by other means. This method has grown in popularity in the past few years because of improvements in accessibility and computational efficiency of latent class estimation procedures. However, there still are issues of estimation and identifiability that should be carefully considered when applying a latent class approach to data.

There are several important further issues to consider. First, the example used here has only considered binary items, but ordinal variables can also be used as observed variables. Second, constraints can be put on parameters in these models, as alluded to in “Identifiability.” For example, if we were interested in a model which includes a class where individuals must report depressed mood, we can constrain the parameter for that class to be 1. Or, if we are willing to acknowledge that there may be some measurement error and that some individuals who actually exhibit depressed mood incorrectly report it, we might want the constraint to be slightly less stringent (i.e., >0.95). Third, there are other models which extend the latent class model by allowing covariates to be associated with the latent class variable.^[20,69] Last, latent class transition models can describe how individuals transition from one class to another over time, and latent growth mixture models can be used to describe latent classes of trajectories over time.^[70,71]

Lilly Reference Ranges

Michael G. Wilson

Butler University, Indianapolis, Indiana, U.S.A.

Abstract

The Lilly Reference Ranges are updated sets of nonparametric reference intervals and delta limits for routine clinical laboratory analyses designed specifically for use in clinical trials. This entry provides several tables and examples to give a detailed illustration of how this type of analysis works.

INTRODUCTION

The Lilly Reference Ranges are updated sets of nonparametric reference intervals and delta limits for routine clinical laboratory analytes designed specifically for use in clinical trials. There are 40 sets of adult reference intervals, 5 sets for each of 8 demographic subgroups, for 39 routine clinical laboratory analytes.^[1] The most recent update of the Lilly Reference Ranges is based on a sample of 20,201 adult patients who were being evaluated for entry into a clinical trial. The sets of reference intervals describe the between patient variability while the delta limits summarize the within patient variability for 39 routine clinical laboratory measurements. Here we present the Lilly Reference Ranges and methods for their construction.

OVERVIEW

In clinical laboratory medicine, reference ranges provide a point of comparison. The interpretation of specific observed laboratory test result is a comparative decision-making process. “Health-associated” reference values are most frequently used to screen patients for the presence of disease, to confirm a diagnosis, and to monitor disease progression. However, the Lilly Reference Ranges are used for very different purposes in the clinical trials setting. For this reason, there are sharp contrasts between “health-associated” reference values and the Lilly Reference Ranges.

In a parallel fashion, Thompson et al.^[2] suggested that three major decisions could be made using observed routine clinical laboratory results in clinical trials. Firstly, patients need to be screened for inclusion in clinical trials. Secondly, patients need to be protected during clinical trials. Thirdly, drugs effects need to be assessed during and after the clinical trial.

The two most striking differences between “health-associated” reference intervals and the Lilly Reference Ranges are that they are narrower and wider, respectively,

and that the reference populations are healthy and clinical trial participants, respectively. However sharp these contrasts are, reference intervals share a similar protocol for their definition and determination.^[3]

METHODS

Thompson et al.^[4] published the methodology for determination of Lilly Reference Ranges in 1987. Briefly, the reference sample was selected by predetermining inclusion and exclusion criteria for all patients entering a clinical trial. The 39 most frequently sampled routine analytes were selected for definition. Written consent was obtained from study participants. Specimens were prepared and collected properly and consistently. Reference value data were inspected to evaluate the distribution. Possible outliers were identified. Methods of estimating reference limits were selected. Reference values were analyzed. Populations were subcategorized for separate reference intervals. These steps are discussed in detail below.

Also in 1987, the approved recommendations on the theory of reference values that provided definitions, principles, and procedures for the determination and use of reference values were published by the Expert Panel on the Theory of Reference Values (EPTRV) of the International Federation of Clinical Chemistry and the Standing Committee on Reference Values of the International Council for Standardization in Hematology. These definitions, principles, and procedures provided a rational approach and sound basis for the determination of reference values.^[5–10]

Subsequently, approved guidelines for the definition and determination of reference ranges were published by the National Committee for Clinical Laboratory Standards (NCCLS) in 1995.^[11] The work of the EPTRV proved to be a most useful basis for the development of the NCCLS guidelines. It was the intent of the subcommittee to publish guidelines for determining “health-associated” reference values. Basically, the a posteriori method as described

by the NCCLS protocol guideline was the methodology employed to construct the Lilly Reference Ranges.

Selection of Reference Sample Group

The reference population is a group consisting of all possible reference individuals. The reference sample group is composed of an adequate number of reference individuals who are selected on the basis of well-defined criteria. The researchers wish to draw inferences from the sample and generalize them to the population.

During the selection of reference individuals, careful consideration should be given to the reference population to which the study is attempting to draw an inference. Unlike, “health-associated” reference intervals, which are very useful diagnostically, Lilly Reference Ranges are used for a very different purpose. Clinical trial researchers dealing with routine clinical laboratory measurements are most interested in testing hypotheses concerning the safety of an experimental compound relative to a control compound. The population for which the researchers are attempting to draw an inference is clinical trial participants. This population generally exhibits greater variability in selected routine laboratory parameters than noted in populations of disease-free individuals. Therefore, Thompson et al. included all clinical trial participants, even if they were not subsequently randomized, with an available reference value in the reference sample group.

Reference values are defined to be those values, or test results, obtained from a reference sample group. The empirical distribution of reference values is defined to be the reference distribution and the summary statistics from the reference distribution used to describe the reference distribution is called a reference limit. These reference limits are commonly order statistics. The interval between, and including, the two reference limits is the reference interval. Few reference intervals should be defined as reference ranges. The term “range” should be reserved for describing a set of values defined by the actual minimal and maximal measured values. Lilly Reference Ranges are defined as such because no trimming or censoring of the distribution occurred and because the minimal and maximal values are available for use.

Potential reference values were only those values for reference individuals that were sampled during qualification for enrollment into a clinical trial. These values were the screening and baseline values for the clinical trial that the reference individuals were screened. Analytes that were used as efficacy variables and not routine laboratory safety variables were excluded as reference values. For example, patients in diabetic studies did not contribute glucose values.

Patients were then to be partitioned into 32 subclasses dichotomizing gender, race, age, smoking, and drinking status. Results for glucose values were to be partitioned into fasting and nonfasting status.

The a posteriori sampling process was used for the Lilly Reference Ranges because the process of exclusion and partitioning took place after analyte testing.

Selection of Sample Size and Statistical Methods for Estimating Reference Limits

In general, reference limits can be determined using parametric or nonparametric methods. Lilly Reference Ranges were determined nonparametrically. There were several considerations for this decision. Nonparametric estimation does not require any assumptions about the distribution for a given analyte. Also, it is a methodology that could be applied consistently for all analytes. It is simple to implement and is readily understandable. The disadvantage of using nonparametric estimation is that when the reference distribution is normal Gaussian, the order statistics are slightly biased and more variable. However, large sample sizes were anticipated for the Lilly Reference Ranges and few distributions were thought to be normally distributed.

The reference value data was inspected to evaluate the reference distribution for each analyte and to identify possible outliers. Because an important implicit assumption is that all routine safety reference values come from the same distribution, none were excluded from the reference distribution or subsequent calculations of the Lilly Reference Ranges regardless of how aberrant they appeared.

However, the primary Lilly Reference Ranges was the 98% interval defined by the 1st and 99th percentiles. The 95% and 90% intervals were also calculated.

Delta Limits

All patients who had repeated measurements during their qualification period were included in the determination of the delta values. These patients had both screening and baseline values. These samples were drawn at an interval of 1 or 2 weeks. This interval was typically associated with the placebo baseline or washout period for their clinical trial.

The difference between the screening and baseline reference values was calculated. A distribution of these differences was defined to be the delta distribution. These differences express the within-patient variability. The same methods for the determination of the reference intervals were applied to these difference values for the creation of the delta limits.

Delta limits can be very useful to the researcher. They provide a guideline for the amount of change that can be expected in a given analyte. This guideline can then be used in the interpretation of the observed change due to an experimental compound for a given patient.

Procedures for validating the reference ranges and delta limits as well as calculating the tolerance intervals were also given by Thompson et al.

^aThe number of adult patients with at least one analyte result is 4801.

RESULTS

The Lilly Reference Ranges are based on a sample of 20,102 patients with at least one analyte result recorded. These patients had blood and urine tests during qualification for entry into 50 clinical trials. A total of 1121 investigators studied 11 indications throughout the United States and Europe. Each of these patients had nonmissing values for gender, race, and age.

This reference population appeared comparable to the U.S. population based as reported in the national almanac on gender, race, age, smoking, and ethanol use. A smoker and imbibor are defined to be those patients who at the screening visit report that they currently smoke or take alcohol. Patients whose baseline value for smoking or ethanol use was missing were deleted from the partitioned interval calculation. Table 1 contains the final sample sizes

for each of the five categorized groups. The NCCLS subcommittee recommends a sample size of 120 reference subjects per analyte.

Each of the five categorized groups were further partitioned into eight groups defined by gender, race, and age. The 98% reference intervals for 39 are shown in Appendix A for the total sample. The 98% intervals for 39

analytes for the remaining 32 demographic groups are contained in Appendices B–E. Electronic copies of Appendices A–E in ASCII format are available from the author by sending a PC formatted diskette with a self-addressed, stamped envelope.

In addition, the results of two blood samples drawn 1 to 4 weeks apart was examined in 5802 patients who were taking placebo at the onset of a clinical trial to calculate delta limits. Not all 20,102 patients had a second blood draw because some failed to meet inclusion criteria, did not take placebo as directed, or did not return for their study. For the patients who did return, their delta values, defined to be the difference between the two blood draws, were included in the reference sample group. The reference distribution was found to be symmetric about zero. Delta limits were not as influenced by demographic factors as were reference ranges so one pair of delta limits was used to describe an analyte. These delta limits are contained in [Appendix A](#).

For the Lilly Reference Range data of 20,102 patients, the Brown–Mood multisample procedure to analytically compare the impact of these five demographic characteristics on the extreme tails. The Brown–Mood procedure is a non-parametric procedure that answers the question: Do patient demographics influence the reference distribution in the tails? The answer “yes” supports the need for partitioning. This procedure was also applied to the delta limits.

The observed significance levels, *p* values, of the Brown–Mood test for the reference ranges are given in [Appendix F](#). These *p* values are derived from the test of the hypothesis for equality between a specific demographic category in tail proportions. This tests whether the proportion of patients with values below the pooled low reference limit is the same for both strata in a demographic category and whether the proportion of patients with values above the pooled high reference limit is the same for both strata in a demographic category defined by each of the five demographic variables. Missing *p* values occur when there are no observations below (above) the reference limit. The observed significance levels, *p* values, of the Brown–Mood test for the delta limits are not reported.

Contained in [Appendix G](#) are the estimates of the difference in the low (high) reference limit between the two strata defined by each of the five demographic variables relative to the low (high) reference limit calculated from the pooled sampled group. For example, the low AST values for females and males are 9 and 10 U/L, respectively. The low AST value for the entire population is 9 U/L. The entry for the low value of AST for gender is $(9 - 10)/9 \times 100 = -11.1\%$.

The sign of each table entry indicates the direction of the difference between reference limits. Missing values are shown for those estimates where the Brown–Mood test was not statistically significant at the 0.05 level.

Some have suggested that for the purposes of clinical trials, disease-specific reference intervals would be helpful. Oesterling et al. have constructed these reference intervals for use in clinical trials specific to detecting early prostate cancer.^[12]

CONCLUSION

We offer an alternative to the use of “health-associated” reference ranges in clinical trials. Unlike Lilly Reference Ranges, many “health-associated” reference ranges do not account for the appropriate population, influential demographic characteristics, adequate sample size, non-normal analyte distributions and within patient variability. Proper use of the Lilly Reference Ranges can lead to more precise safety and efficacy conclusions than the use of such “health-associated” reference ranges in clinical trials.

Local Influence Analysis

Nicola Sartori

Dipartimento di Statistica, Università Cà Foscari di Venezia, Venezia, Italy

Abstract

Local influence analysis is a method for assessing the influence of small perturbations of a statistical model. This entry formalizes the idea of perturbation schemes, addresses likelihood displacement as a measure of sensitivity given to perturbation, and provides an example application in normal linear regression.

INTRODUCTION

Statistical analyses are usually based on models, which are probabilistic descriptions of the process that generated the data. Very often, models involve some unknown parameters of intrinsic interest. These parameters are estimated using the data and lead to the estimated model, which forms the basis for statistical inference. In this sense, a statistical model is a useful device for extracting and understanding the essential features of a set of data. However, the model is almost always only an approximate description of more complicated processes, and hence it is always wrong. Given this inexactness, it is important to study the variation in inference results under modifications of model formulation. In particular, one important concern is that isolated features of the data or specific assumptions of the model should not seriously influence the key results of the analysis.

In general, we may think of influence analysis as a set of methods for assessing the sensitivity of inferences to perturbations in the data or the model. Inferences that are relatively stable across these perturbations should be preferred, even at the cost of some loss in model exactness. On the other hand, inferences that are heavily affected by minor perturbations should be cause of concern. Aspects of the data or the model, which strongly change the results of the analysis, are said to be influential. Case deletion in regression models is an example of data influence diagnostic.^[1] Local influence analysis, introduced by Cook,^[2] is a method for assessing the influence of small perturbations of a statistical model. The method considers changes in the log-likelihood scale as measures to evaluate influential perturbations and, in particular, the analysis is local because such changes are examined in a small neighborhood of the assumed, unperturbed, model.

In the following section on “Perturbation Schemes,” we formalize the idea of perturbation schemes. Then, in section “Likelihood Displacement,” the likelihood displacement is introduced as a measure of sensitivity to a given

perturbation. The local study of the likelihood displacement in a neighborhood of the assumed model is described in section “Local Influence.” As an example an application in normal linear regression is considered. Finally, we end with a brief description of applications and extensions.

PERTURBATION SCHEMES

Let $L(\theta)$ be the log-likelihood of the postulated statistical model, where θ is a p dimensional parameter. Let us assume that we introduce a perturbation in the model formulation through a q dimensional vector ω confined in an open subset Ω of $\mathcal{R}^q$. Let $L(\theta|\omega)$ be the log-likelihood corresponding to the perturbed model for a given ω . We assume that there exists an ω_0 such that $L(\theta) = L(\theta|\omega_0)$, for all θ . We will use $\hat{\theta}$ and $\hat{\theta}_\omega$ to denote the maximum likelihood estimates obtained from $L(\theta)$ and $L(\theta|\omega)$, respectively.

In general, ω can reflect any well-defined perturbation scheme that can be related to data or to model assumptions. Although local influence can be applied in wide generality, as an illustrative example, we will consider the normal linear regression model as the postulated model

$$Y = X\beta + \varepsilon \quad (1)$$

where Y is the $n \times 1$ response variable, X is the $n \times p$ matrix of explanatory variables, β is the $p \times 1$ vector of regression coefficients, and $\varepsilon \sim N_n(0, \sigma^2 I_n)$.

The parameter is then $\theta = (\beta, \sigma^2)$, and the log-likelihood is

$$L(\theta) = -\frac{n}{2} \log \sigma^2 - \frac{1}{2\sigma^2} (Y - X\beta)^T (Y - X\beta)$$

Examples of perturbation schemes are as follows:

1. Response perturbations: in model (1), Y is replaced by $Y + \omega$. Hence, ω has dimension $q = n$ and $\omega_0 = 0$.

2. Predictor perturbations: we may perturb, for instance, the i th column of X , X_i , with $X_i + \omega$. Even in this case, $q = n$ and $\omega_0 = 0$.
3. Variances perturbations: we can change the assumption of homoscedasticity replacing the variance of ε in Eq. (1), with $\sigma^2 W^{-1}$, where $W = \text{diag}(\omega_1, \omega_2, \dots, \omega_n) = \text{diag}(\omega)$. Hence $q = n$ and $\omega_0 = 1$. We note that, when a particular ω_j approaches 0, the analysis corresponds to the deletion of the j th observation. For this reason, this is a generalization of deletion diagnostics, such as Cook's distance,^[1] and is also addressed as case-weight perturbation.^[3]

The first two schemes are perturbations of the data, while the third one is a perturbation of an assumption of the model. Other examples of perturbation schemes in the linear model may be found in Refs. [3,4].

LIKELIHOOD DISPLACEMENT

A comparison of $\hat{\theta}$ and $\hat{\theta}_\omega$ is one way of assessing the influence of a particular perturbation ω . If the difference between $\hat{\theta}$ and $\hat{\theta}_\omega$ is not large, when ω varies in Ω , then inference is stable. However, it is not easy to compare these estimates when the dimension p is large. Moreover, different elements of $\hat{\theta}$ may be in different units and estimated with different precisions. In fact, it is more convenient to judge the distance between $\hat{\theta}$ and $\hat{\theta}_\omega$ with a scalar real-valued function based on the likelihood, even because in likelihood analyses, it is the likelihood itself that summarizes the essential inference information.

Cook^[2] introduces the likelihood displacement

$$LD(\omega) = L(\hat{\theta}) - L(\hat{\theta}_\omega) \quad (2)$$

as a measure for assessing the difference between $\hat{\theta}$ and $\hat{\theta}_\omega$. The likelihood displacement is a non-negative function, which is zero in the postulated model, $LD(\omega_0) = 0$, and that is large when influence is present. We note that $L(\theta|\omega)$ is used only to obtain the estimate $\hat{\theta}_\omega$.

LOCAL INFLUENCE

The plot of $LD(\omega)$ as ω varies in Ω is called the influence graph, and it can be a useful tool to explore the presence of influence. However, this is rarely possible in practical situation, say when $q \leq 2$. Moreover, in general, an influence graph requires the evaluation of $\hat{\theta}_\omega$ for each value of ω which, in some models, may be a computationally intensive task.

One possible solution is to study the local behavior of Eq. (2) in a neighborhood of the postulated model, that means, in a neighborhood of ω_0 . Given a direction d in Ω

of unit length, we can study the behavior of $LD(\omega_0 + ad)$ as a function of the scalar a . As the likelihood displacement achieves a minimum in ω_0 , the graph of $LD(\omega_0 + ad)$ has a minimum at $a = 0$. For this reason, Cook^[2] proposed to use the normal curvature $C(d)$ of $LD(\omega + ad)$ around $a = 0$. A large curvature means that $LD(\omega + ad)$ is changing rapidly at $a = 0$ in the direction d . Therefore, the direction of maximum curvature, $d_{\max} = \text{argmax } C(d)$, gives the direction in which $LD(\omega)$ is changing most rapidly around ω_0 .

The normal curvature in the direction d is defined as

$$C(d) = 2|d^T F d|$$

where $F = \partial^2 L(\hat{\theta}_\omega) / \partial \omega \partial \omega^T$, evaluated at $\theta = \hat{\theta}$ and $\omega = \omega_0$. Using chain rule for differentiation, we can write

$$F = \left[\frac{\partial^2 L(\hat{\theta}_\omega)}{\partial \omega \partial \omega^T} \right]_{\hat{\theta}, \omega_0} = \Delta(\hat{\theta}, \omega_0)^T J(\hat{\theta})^{-1} \Delta(\hat{\theta}, \omega_0)$$

where $\Delta(\theta, \omega) = \partial^2 L(\theta|\omega) / \partial \theta \partial \omega^T$ and $J(\theta) = -\partial^2 L(\theta) / \partial \theta \partial \theta^T$ is the observed information matrix. Hence, it follows that

$$C(d) = 2 \left| d^T \Delta(\hat{\theta}, \omega_0)^T J(\hat{\theta})^{-1} \Delta(\hat{\theta}, \omega_0) d \right| \quad (3)$$

Note that all quantities in Eq. (3) are evaluated at $\theta = \hat{\theta}$ and $\omega = \omega_0$, which are quantities of the unperturbed model.

The maximum curvature $C_{\max} = \max C(d)$ is equal to twice the largest eigenvalue of F . The corresponding eigenvector is then the direction of maximum curvature $d_{\max}$. The direction of maximum curvature is the main diagnostic tool that comes with this method. A plot of the elements of $d_{\max}$ may help to identify which components of ω are relatively most influential. Moreover, to assess the presence of local influence in the direction $d_{\max}$, it is possible to plot relevant statistics against the perturbation $\omega(a) = \omega_0 + a d_{\max}$. For instance, we may plot $LD(\omega(a))$ against a or plot elements of $\hat{\theta}_\omega(a)$ against a . We note that the direct interpretation of $C_{\max}$ itself is not recommended, as it depends on the chosen scale for ω , while $d_{\max}$ does not.

When the interest is in a subset of the whole parameter, we consider a different likelihood displacement. Indeed, let us assume that $\theta^T = (\theta_1^T, \theta_2^T)$ and that only θ_1 is of direct interest. Hence, we define the likelihood displacement for the subset θ_1 as

$$LD_1(\omega) = 2 \left\{ L(\hat{\theta}) - L(\theta_{1\omega}, c(\hat{\theta}_{1\omega})) \right\}$$

where $c(\theta_1)$ is the function that maximizes $L(\theta_1, \theta_2)$ for each fixed θ_1 , and $\hat{\theta}_{1\omega}$ is determined by the partition $\hat{\theta}_\omega^T = (\hat{\theta}_{1\omega}^T, \hat{\theta}_{2\omega}^T)$. In Ref. [2], section 3.2, it is shown that the normal curvature for $LD_1(\omega)$ has the form

$$C_1(d) = 2 \left| d^T \Delta(\hat{\theta}, \omega_0)^T \left\{ J(\hat{\theta})^{-1} - B_{22} \right\} \Delta(\hat{\theta}, \omega_0) d \right| \quad (4)$$

where

$$B_{22} = \begin{pmatrix} 0 & 0 \\ 0 & J_{22}(\hat{\theta})^{-1} \end{pmatrix}$$

and $J_{22}(\theta)$ is the block of the information matrix $J(\theta)$ corresponding to θ_2 . Hence, in this case $d_{\max}$ is the eigenvector corresponding to the maximum eigenvalue of $\Delta(\hat{\theta}, \omega_0)^T \{J(\hat{\theta})^{-1} - B_{22}\} \Delta(\hat{\theta}, \omega_0)$.

AN EXAMPLE

As a numerical illustration, let us consider the geese data for observer 1.^[5] The data consist of observations on true flock size obtained by aerial photographs (y) and a visual estimation of the flock size made by the observer (x) on 45 flocks of snow geese. We use a simple linear regression as given by Eq. (1) to illustrate the behavior of $d_{\max}$ in the presence of heteroscedasticity. In particular, as in Ref. [2], section 4.4, we use a case-weights perturbation scheme, as illustrated in point 3 at the end of section “Perturbation Schemes.”

The log-likelihood is given by

$$L(\theta | \omega) = -\frac{n}{2} \log \sigma^2 - \frac{1}{2\sigma^2} (Y - X\beta)^T W (Y - X\beta)$$

and, assuming that only coefficients β are of interest, the normal curvature [Eq. (4)] is given by

$$C_1(d) = 2d^T \text{diag}(e) X (X^T X)^{-1} X^T \text{diag}(e) d / \hat{\sigma}^2$$

where e is the vector of observed residuals of the postulated model.

The maximum curvature $C_{\max}$ is the largest eigenvalue of the matrix $\text{diag}(e) X (X^T X)^{-1} X^T \text{diag}(e)$ and is equal to 14.39. The corresponding eigenvector $d_{\max}$ is the direction of maximum local influence. A plot of the absolute values of the elements of $d_{\max}$ is given in Fig. 1, showing that observations 29, 28, and 41 are mostly locally influential (relatively to the others). Fig. 2 shows a plot of the elements of $d_{\max}$ vs. the observer counts (x) and gives a clear indication of heteroscedasticity. In this example, $d_{\max}$ is a useful tool to direct attention to cases where specification of weights can be most important.

APPLICATIONS AND EXTENSIONS

Local influence analysis is a diagnostic tool that allows to check if the results of inference are affected by local perturbations of model assumptions. Because it is based on changes in the log-likelihood scale, its use can be quite general, and several applications have been proposed in the literature. Some are listed below.

Fig. 1 Geese data. Absolute values of the elements of $d_{\max}$

Fig. 2 Geese data. Elements of $d_{\max}$ vs. observer counts (x)

When Cook^[2] introduced local influence, he considered several perturbation schemes but mainly restricted to normal linear regression. A recent review is also given in Ref. [4]. An extension to linear mixed models is given in Refs. [6,7]. Normal non-linear models are considered in Refs. [8,9], while generalized linear models are considered in Refs. [10–12] and, with the addition of random effects, in Ref. [13]. Local influence related to different aspects of the proportional hazards model is studied in Refs. [14–18]. An adaptation of local influence methods to regression analyses with censoring is given in Ref. [19], while problems with incomplete data are investigated in Refs. [20,21].

Finally, we note that the lack of invariance of the normal curvature $C_{\max}$ with respect to the scale of the perturbation scheme has sometimes raised some concern, and variants and extensions of Cook's approach have been proposed in the literature.^[22–27] However, local influence should be viewed mainly as a diagnostic tool and the main tool that comes with this method, which is the direction of maximum curvature $d_{\max}$, is invariant with respect to reparameterizations of the perturbation scheme.

Abstract

This entry is focused on the analysis of the last observations, which are defined as observations from the last time point for patients who completed the study and the last observations prior to the dropout for patients who did not complete the study.

INTRODUCTION

In clinical trials, data are often collected over a period of time from participating patients. In many situations, however, analyses are only based on data from the last time point (the end of the study) or change from the baseline to the last time point. It is often the case that patients drop out before the completion of the study. Heyting et al.^[1] summarized six common reasons for patient dropout: (1) recovery; (2) lack of improvement; (3) side effect; (4) unpleasantness; (5) intercurrent health problems; and (6) external factors unrelated to trials. These reasons indicate that the dropout rate is often informative in the sense that the population of patients who completed the study is different from the population of patients who dropped out.

In this entry, we focus on the analysis of the last observations, which are defined as observations from the last time point for patients who completed the study and the last observations prior to the dropout for patients who did not complete the study. An analysis based only on data from patients who completed the study is called a completers analysis. Although a *completers analysis* is sufficient in some situations, it is often more desirable to perform an *all randomized subjects* analysis. The analysis based on all randomized subjects is usually referred to as an intention-to-treat (ITT) analysis. Regulatory agencies generally consider the ITT analysis as the primary analysis for evaluation of efficacy and safety in clinical trials with informative dropout (see, e.g., Refs. [2–4]). When the dropout is informative, the target populations of a completers analysis and an ITT analysis are different. Suppose that the population of patients under certain treatment is stratified according to the time of the last observations; then the target population of a completers analysis is only the subpopulation of patients who completed the study under different treatments while the target populations of an ITT analysis include all the subpopulations under different treatments.

For the last observation carry-forward (LOCF) analysis based on ITT population, the last observations are carried forward to the last time point for patients who dropped out. The LOCF analysis treats the carried-forward data as observed data at the last time point. Therefore when the dropout is informative, the LOCF analysis may introduce biases to the statistical inference, which has been speculated upon by the Food and Drug Administration (FDA) in its website (see also Ref. [5]). Although there are discussions, examples, and limited empirical results available in the literature (e.g., Refs. [1,6–8]) regarding this subject, it is still unknown whether or not the LOCF test is asymptotically correct (i.e., its asymptotic size is equal to the nominal size). In this entry, we outline results from Shao and Zhong^[5,9] and Cheng and Shao,^[10] which addressed the above question under the one-way and two-way analysis of variance (ANOVA) models. It is shown that, under certain circumstances, the LOCF test is still asymptotically correct. When the LOCF tests are biased, alternatively, we describe simple but asymptotically correct tests. The proposed tests do not require model assumptions that are nonverifiable by the existing data as pointed out by the FDA.^[2]

Overview

In the section “Validity of the LOCF Test Under a One-Way ANOVA Model,” the LOCF test under a one-way ANOVA model is studied. In the section “Validity of the LOCF ANOVA Test Under a Two-Way ANOVA Model,” we examine the LOCF test under the two-way ANOVA model with and without an interaction for assessing treatment effects, respectively. When the LOCF test is invalid, an alternative asymptotically correct test is proposed in the section “Asymptotically Correct Tests.” The proposed test is illustrated through an example concerning an ITT analysis under a one-way ANOVA model. A brief discussion is given in “Conclusion.”

VALIDITY OF THE LOCF TEST UNDER A ONE-WAY ANOVA MODEL

Consider a parallel-group design for comparing $I \geq 2$ treatments, one of which could be a placebo or an active control. Suppose a total of n patients are randomly assigned to the I treatment groups, where the i th group has n_i patients, $i = 1, \dots, I$. Suppose that patients are evaluated at S time points. Let μ_{is} be the mean of the response under the i th treatment at the last visit. If there is no dropout, then the usual one-way ANOVA test is useful for testing the following null hypothesis

$$H_0: \mu_{1S} = \dots = \mu_{IS} \quad (1)$$

based on the last observations from all patients.

Suppose that, in the i th group, n_{is} patients drop out after the s th visit. Note that n_{is} 's are random but satisfy the constraint $\sum_{s=1}^S n_{is} = n_i$. When there are dropouts in the trial, it is not appropriate to test the null hypothesis (Eq. 1). Under an ITT analysis, the patient population under the treatment i consists of S subpopulations, where the s th subpopulation is the population of patients who are on therapy and drop out after the s th visit (the subpopulation with $s = S$ corresponds to the population of completers). Let μ_{is} be the mean of the s th subpopulation under treatment i , the global mean of the i th treatment group is then

$$\mu_i = \sum_{s=1}^S p_{is} \mu_{is}$$

where p_{is} is the true proportion of patients in the s th subpopulation under treatment i . If we use the global means as the measure of the treatment effect, then the null hypothesis of no treatment effect should be formulated as

$$H_0: \mu_1 = \dots = \mu_I \quad (2)$$

McHugh and Matts^[11] discussed a similar measure for the treatment effect. Note that the two null hypotheses (Eqs. 1 and 2) are different when the dropout is informative.

Let y_{isl} be the last observed response from the l th subject in the group of patients who drop out after the s th visit. The LOCF analysis treats y_{isl} as the unobserved y_{iSl} when $s < S$ and applies the usual one-way ANOVA test. That is, the LOCF test concludes that there is a treatment effect if and only if

$$\frac{\text{MSTR}}{\text{MSE}} > F_{I-1, n-I, \alpha}$$

where $F_{I-1, n-I, \alpha}$ is the $(1 - \alpha)$ th quantile of the F -distribution with $I - 1$ and $n - I$ degrees of freedom and α is the level of significance,

$$\text{MSTR} = \frac{1}{I-1} \sum_{i=1}^I n_i (\bar{y}_{i..} - \bar{y}_{...})^2$$

$$\text{MSE} = \frac{1}{n-I} \sum_{i=1}^I \sum_{s=1}^S \sum_{l=1}^{n_{is}} (y_{isl} - \bar{y}_{i..})^2$$

where

$$\bar{y}_{i..} = \frac{1}{n_i} \sum_{s=1}^S \sum_{l=1}^{n_{is}} y_{isl}$$

and

$$\bar{y}_{...} = \frac{1}{n} \sum_{i=1}^I \sum_{s=1}^S \sum_{l=1}^{n_{is}} y_{isl}$$

In practice, an interesting question arises. When the dropout is informative, what is the null hypothesis dose the resultant LOCF test for, especially, when the observed MSTR/MSE value is large? Considering that MSTR will be large when the difference among $\bar{y}_{i..}$, $i = 1, \dots, I$, is large, it is reasonable to say that the null hypothesis for the LOCF test is the null hypothesis H_0 given in Eq. 2. However, treating y_{isl} as the unobserved y_{iSl} makes one think that the LOCF test preassumes that $\mu_{is} = \mu_{iS} = \mu_i$ for all s (i.e., dropout is noninformative). When the dropout is noninformative, the size of the LOCF test is exactly equal to the nominal size α when y_{isl} 's are independent and normally distributed with a constant variance σ^2 and approximately equal to α when the normality assumptions is removed but n_i 's are large for all i . But what is the behavior of the LOCF test when the dropout is informative, i.e., when $\mu_{is} \equiv \mu_i$ is not true?

Intuitively, the LOCF test cannot be correct or asymptotically correct when the dropout is informative. Surprisingly, Shao and Zhong^[5] showed that, in some cases, the LOCF test is still valid even if the dropout is informative. The following theorem, proved in Shao and Zhong,^[5] fully characterizes the validity of the LOCF test under a one-way ANOVA model.

Theorem 1

Suppose that y_{isl} 's are independent with $E(y_{isl}) = \mu_{is}$ and $\text{Var}(y_{isl}) = \sigma^2$ and that $p_{is} > 0$ for all i, s .

- As $n_i \rightarrow \infty$ for all i ,

$$\text{MSE} \rightarrow_p \sigma^2 + b \quad (3)$$

where $\rightarrow_p$ means convergence in probability and

$$b = \lim \frac{1}{n-I} \sum_{i=1}^I (n_i - 1) \tau_i^2$$

where

$$\tau_i^2 = \sum_{s=1}^S p_{is} (\mu_{is} - \mu_i)^2 \quad (4)$$

- ii. When $I = 2$, under H_0 in Eq. 2,

$$MSTR \rightarrow_d (\sigma^2 + a)\chi_1^2 \quad (5)$$

where $\rightarrow_d$ means convergence in distribution and

$$a = \lim_{I \rightarrow \infty} \frac{1}{I-1} \sum_{i=1}^I \left(1 - \frac{n_i}{n}\right) \tau_i^2$$

Furthermore, if μ_i 's are related so that

$$c = \lim_{I \rightarrow \infty} \frac{1}{I-1} \sum_{i=1}^I n_i \left(\mu_i - \frac{1}{n} \sum_{i=1}^I n_i \mu_i \right)^2$$

is finite, then

$$MSTR \rightarrow_d (\sigma^2 + a)\chi_1^2 \left(\frac{c}{\sigma^2 + a} \right) \quad (6)$$

where $\chi_q^2(\delta)$ denotes a noncentral chi-square random variable with q degrees of freedom and the noncentrality parameter δ . We adopt this notation throughout this paper and when $\delta = 0$, $\chi_q^2(0)$ is abbreviated as χ_q^2 , the central chi-square random variable.

- iii. When $I \geq 3$, under H_0 in Eq. 2, MSTR converges in distribution to a linear combination of $I - 1$ independent central chi-square random variables with 1 degree of freedom.

As can be observed in Theorem 1, in the special case that $I = 2$ treatments, the asymptotic size (when $n_i \rightarrow \infty$) of the LOCF test, when H_0 in Eq. 2 is used as the null hypothesis, is less than or equal to the nominal level α if and only if $a \leq b$, or, equivalently,

$$\lim \left(\frac{n_2 \tau_1^2}{n} + \frac{n_1 \tau_2^2}{n} \right) \leq \lim \left(\frac{n_1 \tau_1^2}{n} + \frac{n_2 \tau_2^2}{n} \right) \quad (7)$$

where τ_i^2 is defined in Eq. 4. If n_1 and n_2 are almost the same, i.e., $\lim \frac{n_1}{n} = \lim \frac{n_2}{n}$, then the equality holds and the LOCF test is asymptotically correct in the sense that the asymptotic size of the LOCF test is α regardless of whether or not the dropout is informative. When $\lim \frac{n_1}{n} \neq \lim \frac{n_2}{n}$, the asymptotic size of the LOCF test is not α unless $\tau_1^2 = \tau_2^2$. However, in practice, this occurs only when $\tau_1^2 = \tau_2^2 = 0$, i.e., $\mu_{is} \equiv \mu_i$ for all s , that means the dropout is noninformative.

When $I = 2$ but $\tau_1^2 \neq \tau_2^2$ and $n_1 \neq n_2$, the LOCF test has an asymptotic size smaller than α if

$$(n_2 - n_1)\tau_1^2 < (n_2 - n_1)\tau_2^2 \quad (8)$$

or larger than α if $<$ in Eq. 8 is replaced by $>$. If treatment 1 is the placebo, then often $n_1 < n_2$ and $\tau_1^2 < \tau_2^2$ (i.e., the

variation among μ_{2s} 's is larger than that among μ_{1s} 's) and therefore Eq. 8 holds and the LOCF test is too conservative in the sense that its size is too small. Note that if the size of a test is unnecessarily small, the power of detecting treatment effects is unnecessarily low, which is a disadvantage for the drug companies.

When $I \geq 3$, the asymptotic size of the LOCF test when H_0 is used as the null hypothesis is generally not α .

VALIDITY OF THE LOCF ANOVA TEST UNDER A TWO-WAY ANOVA MODEL

Consider a parallel-group design for comparing I treatments, one of which could be a placebo or an active control. Suppose a total of n patients are randomly assigned to I treatment groups and J treatment centers, where the i th treatment group has n_i patients ($i = 1, \dots, I$) and of which n_{ij} patients at center j ($j = 1, \dots, J$). The proportion of patients allocated to treatment i at center j is fixed as $p_{ij} = (n_{ij}/n_i > 0)$. Suppose that patients are scheduled to be evaluated at S postbaseline time points (visits) to complete the study. However, owing to some reasons, in the i th treatment and j th center, at the s th visit ($s = 1, \dots, S$), n_{ijs} patients have their evaluations valued as y_{ijsl} , $l = 1, \dots, n_{ijs}$ and then drop out after the visit. Note that n_{ijs} 's are random but they satisfy the constraint $\sum_{s=1}^S n_{ijs} = n_{ij}$.

Similar to the case of one-way ANOVA, under the ITT analysis, the patient population under the treatment i at the center j consists of S subpopulations, where the (i, j, s) th population is the population of patients who are on therapy i at the center j and who drop out after the s th visit. Let μ_{ijs} be the mean of the (i, j, s) th subpopulation. Then global mean of the patient population under the treatment i is

$$\mu_i = \sum_{j=1}^J p_{ij} \sum_{s=1}^S p_{ijs} \mu_{ijs}$$

where p_{ijs} is the true proportion of patients in the (i, j, s) th subpopulation under the treatment i at center j . If we use the global mean as the measure of treatment effect, then the null hypothesis of no treatment effect should be

$$H_0 : \mu_1 = \dots = \mu_I \quad (9)$$

Two-Way ANOVA Model Without Interaction

In some cases, it may be reasonable to assume that there is no interaction between the treatments and centers in the sense that the change of the treatments is not affected across the centers. Under the additive two-way ANOVA model, the ITT LOCF test assumes treatment and center

as fixed factors and concludes that a treatment effect exists if and only if

$$\frac{\text{MSTR}}{\text{MSE}} > F_{I-1, n-I, \alpha}$$

where

$$\text{MSTR} = \frac{1}{I-1} \sum_{i=1}^I n_i (\bar{y}_{i...} - \bar{y}_{...})^2$$

$$\text{MSE} = \frac{1}{n-IJ} \sum_{i=1}^I \sum_{j=1}^J \sum_{s=1}^S \sum_{l=1}^{n_{ijs}} (y_{ijsl} - \bar{y}_{ij..})^2$$

$$\bar{y}_{i...} = \frac{1}{n_i} \sum_{j=1}^J \sum_{s=1}^S \sum_{l=1}^{n_{ijs}} y_{ijsl}, \quad \bar{y}_{...} = \frac{1}{n} \sum_{i=1}^I \sum_{j=1}^J \sum_{s=1}^S \sum_{l=1}^{n_{ijs}} y_{ijsl}$$

and

$$\bar{y}_{ij..} = \frac{1}{n_{ij}} \sum_{s=1}^S \sum_{l=1}^{n_{ijs}} y_{ijsl}$$

The following theorem, given in Shao and Zhong,^[9] summarizes the properties of the LOCF test under the additive model.

Theorem 2

Suppose that y_{ijsl} 's are independent with $\mu_{ijs} = E(y_{ijsl})$ and $\text{Var}(y_{ijsl}) = \sigma^2$ and that $p_{ijs} > 0$ for all i, j, s . Denote

$$\mu_{ij} = \sum_{s=1}^S p_{ijs} \mu_{ijs}, \quad \mu_i = \sum_{j=1}^J p_{ij} \mu_{ij}$$

$$\tau_{ij}^2 = \sum_{s=1}^S p_{ijs} (\mu_{ijs} - \mu_{ij})^2, \quad \tau_i^2 = \sum_{j=1}^J p_{ij} \tau_{ij}^2$$

and

$$\bar{y}_{ij..} = \frac{1}{n_{ij}} \sum_{s=1}^S \sum_{l=1}^{n_{ijs}} y_{ijsl}$$

i. As $n \rightarrow \infty$,

$$\text{MSE} \rightarrow_p \sigma^2 + b \quad (10)$$

where

$$b = \lim \frac{1}{n-IJ} \left(\sum_{i=1}^I n_i \tau_i^2 - \sum_{i=1}^I \frac{1}{n_i} \sum_{j=1}^J \tau_{ij}^2 \right) \quad (11)$$

ii. Under the additive two-way ANOVA model, when $I = 2$, if μ_i 's are related so that

$$c = \lim \sum_{i=1}^2 n_i \left(\mu_i - \frac{1}{n} \sum_{i=1}^2 n_i \mu_i \right)^2$$

is finite, then

$$\frac{\text{MSTR}}{\text{MSE}} \rightarrow_d \frac{\sigma^2 + a}{\sigma^2 + b} \chi_1^2 \left(\frac{c}{\sigma^2 + a} \right) \quad (12)$$

where

$$a = \lim \sum_{i=1}^2 \left(1 - \frac{n_i}{n} \right) \tau_i^2 \quad (13)$$

Furthermore, under H_0 in Eq. 9,

$$\frac{\text{MSTR}}{\text{MSE}} \rightarrow_d \frac{\sigma^2 + a}{\sigma^2 + b} \chi_1^2 \quad (14)$$

iii. Under the additive two-way ANOVA model, when $I \geq 3$, under H_0 in Eq. 9, MSTR converges in distribution to a linear combination of independent central chi-square random variables with 1 degree of freedom.

When there are only two treatment groups (i.e., $I = 2$), Theorem 2 implies that the LOCF test is asymptotically correct if $\lim \frac{n_1}{n} = \lim \frac{n_2}{n}$. That is, when n_1 and n_2 are nearly similar, regardless of whether the dropout is informative or not. And when $\lim \frac{n_1}{n} \neq \lim \frac{n_2}{n}$, the asymptotic size of LOCF test is not α unless the dropout is noninformative. When $\tau_1^2 \neq \tau_2^2$ and $n_1 \neq n_2$, the LOCF test has an asymptotic size smaller than α if

$$(n_2 - n_1) \tau_1^2 < (n_2 - n_1) \tau_2^2 \quad (15)$$

or larger than α if $<$ in Eq. 8 is replaced by $>$. If treatment 1 represents the placebo, then it is often the case that $n_1 < n_2$ and $\tau_1^2 < \tau_2^2$ (i.e., the variation among μ_{2js} 's is larger than that among μ_{1js} 's) and therefore Eq. 8 holds and the LOCF test is too conservative in the sense that its size is too small. Note that if the size of a test is unnecessarily small, the power of detecting treatment effects is unnecessarily low, which is a disadvantage for the drug companies.

When $I \geq 3$, the asymptotic size of the LOCF test when H_0 in Eq. 9 is used as the null hypothesis is generally not α .

Two-Way ANOVA Model with Interaction

In many situations, it may not be appropriate to assume an additive model in the first place. If that is the case, we have to consider a two-way ANOVA model with interaction between the treatments and centers. To test the treatment effect for the two-way ANOVA model with interaction, the interaction effect has to be tested first.

Otherwise, the result for testing the treatment effect cannot be interpreted in a statistically meaningful manner. It is widely recognized that in testing the interaction, when the design is unbalanced, there exists no closed form based on the usual ANOVA method (i.e., the method of sum of squares). To give a clear description of the LOCF test under the interaction model, we consider the balanced case when $n_{ij} \equiv m > 1$, and denote $n_{ijs} = m_s$. When testing for the interaction, the LOCF test concludes that there is an interaction effect if

$$\frac{MSAB}{MSE} > F_{(I-1)(J-1), IJ(m-1), \alpha}$$

where

$$MSAB = \frac{m}{(I-1)(J-1)} \sum_{i=1}^I \sum_{j=1}^J \times (\bar{y}_{ij..} - \bar{y}_{i...} - \bar{y}_{.j..} + \bar{y}_{....})^2$$

and

$$\begin{aligned} \bar{y}_{ij..} &= \frac{1}{m} \sum_{s=1}^S \sum_{l=1}^{m_s} y_{ijsl} \\ \bar{y}_{i...} &= \frac{1}{mJ} \sum_{j=1}^J \sum_{s=1}^S \sum_{l=1}^{m_s} y_{ijsl} \\ \bar{y}_{.j..} &= \frac{1}{mI} \sum_{i=1}^I \sum_{s=1}^S \sum_{l=1}^{m_s} y_{ijsl} \\ \bar{y}_{....} &= \frac{1}{mIJ} \sum_{i=1}^I \sum_{j=1}^J \sum_{s=1}^S \sum_{l=1}^{m_s} y_{ijsl} \end{aligned}$$

The following result addresses the question regarding the validity of the LOCF test in the balanced case (see, e.g., Ref. [10]).

Theorem 3

Under the balanced two-way ANOVA model with interaction,

- i. *when $I = J = 2$, as $m \rightarrow \infty$, for testing of interaction, the LOCF test is asymptotically correct;*
- ii. *when $I = 2$ and $J \geq 3$, for testing Eq. 2, a sufficient condition for LOCF to be valid is τ_{ij}^2 are the same for each fixed i , where $\tau_{ij}^2 = \sum_{s=1}^S p_{ijs} (\mu_{ijs} - \mu_{ij})^2$.*

In the unbalanced case, the LOCF test is much more complicated. Cheng and Shao^[10] proved the following result:

Theorem 4

Assume the unbalanced two-way ANOVA model with interaction. When $I = J = 2$, as $n_{ij} \rightarrow \infty$, the LOCF test is asymptotically valid for testing Eq. 2 if

$$\lim \frac{n_{11}}{n} = \lim \frac{n_{12}}{n} = \lim \frac{n_{21}}{n} = \lim \frac{n_{22}}{n}$$

that is, the cell frequencies n_{11} , n_{12} , n_{21} , and n_{22} are nearly the same, or the design is almost balanced. When $I = J = 2$ is not true, the asymptotic size of the LOCF test for interaction is generally not α .

The above theorem indicates that, under the two-way ANOVA model with interaction, the LOCF test for treatment effect is valid only for the very special case consisting of two treatments and two centers—which is not practically possible. For all the other cases, the asymptotic size of the LOCF test for treatment effect described in the section “Two-way ANOVA Model Without Interaction” is generally not equal to the nominal size α .

ASYMPTOTICALLY CORRECT TESTS

We have shown that the LOCF test is asymptotically correct in some special situations. In those situations, the LOCF method may be used because of its simplicity. However, when the LOCF test for treatment effect is invalid (in the sense that its asymptotic size is not equal to the nominal size α), asymptotically correct tests should be used. Under the one-way ANOVA model, it is recommended that the test proposed by Shao and Zhong,^[5] which is always asymptotically valid, be used.

Not that the poststratified sample mean under treatment i can be written as

$$\hat{\mu}_i = \sum_{s=1}^S \frac{n_{is}}{n_i} \bar{y}_{is.} = \frac{1}{n_i} \sum_{s=1}^S \sum_{l=1}^{n_{is}} y_{isl} = \bar{y}_{i..}$$

It can be verified that $\hat{\mu}_i$ is an unbiased estimator of μ_i and its variance is

$$V_i = \frac{1}{n_i} \left(\sum_{s=1}^S p_{is} \sigma_{is}^2 + \tau_i^2 \right)$$

where $\sigma_{is}^2 = \text{Var}(y_{isl})$. Note that σ_{is}^2 's are allowed to be different. An approximately unbiased estimator of V_i is

$$\hat{V}_i = \frac{1}{n_i(n_i - 1)} \sum_{s=1}^S \sum_{l=1}^{n_{is}} (y_{isl} - \bar{y}_{i..})^2$$

Define

$$T = \sum_{i=1}^I \frac{1}{\hat{V}_i} \left(\bar{y}_{i..} - \frac{\sum_{i=1}^I \bar{y}_{i..} / \hat{V}_i}{\sum_{i=1}^I 1 / \hat{V}_i} \right)^2$$

Thus we have the following result (see Ref. [5]).

Table 1 Subpopulation Parameters

Parameter	Treatment $i = 1$ (placebo)				Treatment $i = 2$ (drug)			
	Visit 1	Visit 2	Visit 3	Global	Visit 1	Visit 2	Visit 3	Global
p_{ij}	0.20	0.20	0.60		0.15	0.15	0.70	
μ_{ij}	25	24	21		40	32	16.6	
σ_{ij}^2	100	100	100		100	100	100	
μ_I				22.4				22.4
τ_i^2				3.04				84.1

Table 2 Simulation Result (2000 Simulations)

$n_1 + n_2$	$p_1 = 30\%$		$p_1 = 50\%$		$p_1 = 70\%$	
	LOCF test	SZ test	LOCF test	SZ test	LOCF test	SZ test
40	0.0275	0.0600	0.0465	0.0535	0.0690	0.0555
80	0.0295	0.0540	0.0485	0.0520	0.0740	0.0520
160	0.0285	0.0540	0.0460	0.0460	0.0755	0.0480

Theorem 5

Under the hypothesis H_0 in Eq. 2, as $n_i \rightarrow \infty$ for all i ,

$$T \rightarrow_d \chi_{I-1}^2$$

Furthermore, if μ_i 's are related so that

$$\tilde{c} = \lim \sum_{i=1}^I \frac{1}{V_i} \left(\mu_i - \frac{\sum_{i=1}^I \mu_i / V_i}{\sum_{i=1}^I 1/V_i} \right)^2$$

is finite, then

$$T \rightarrow_d \chi_{I-1}^2(\tilde{c})$$

An Example

To illustrate the performance of the LOCF test and the test suggested by Shao and Zhong^[5] (SZ test), we present part of the simulation result in Shao and Zhong.^[5] We consider the case when there are two treatments and the total number of complete visits is three for each treatment (i.e., $I = 2$, $S = 3$). The subpopulations are normally distributed with the following parameters (Table 1).

The parameters for the subpopulations are chosen such that the global means are similar for the two treatments while the means for the subpopulations are so dispersed that τ_1^2 and τ_2^2 are very different.

For the fixed nominal level of significance $\alpha = 0.05$, the simulated (approximated) probability of type 1 error (based on 2000 simulations) are presented for the total sample size $n = n_1 + n_2 = 40, 80, 160$, respectively. And

for each fixed sample size, three different percentage of n_1 in $n = n_1 + n_2$, namely, $p_1 = n_1/n = 30\%, 50\%, 70\%$ are considered. The simulation result is given in the following table.

Table 2 indicates that when $p_1 = 50\%$, i.e., when $n_1 = n_2$, the probability of the type 1 error of the LOCF test is close to $\alpha = 0.05$, but is considerably small when $p_1 = 30\%$ while considerably large when $p_1 = 70\%$. The probability of the type 1 error of Shao and Zhong^[5] test is close to α regardless of whether n_i 's are equal or not.

Note that under the two-way ANOVA model, the construction of asymptotically correct tests is more complicated. More details can be found in Cheng and Shao^[10] and Shao and Zhong.^[9]

CONCLUSION

We have shown that the LOCF test is asymptotically correct in some special situations, where the LOCF method may be used because of its simplicity. However, when the LOCF test for treatment effect is invalid (in the sense that its asymptotic size is not equal to the nominal size α), asymptotically correct tests should be used. Under the one-way ANOVA model, it is recommended that the asymptotically correct test proposed by Shao and Zhong^[5,9] or Cheng and Shao^[10] be used.

The validity of LOCF examined in this entry does not incorporate the influence of clinical relevant variables such as demographics and patient characteristics (e.g., disease status and/or medical history) at baseline. In practice, it is suggested that those variables be included in the model for evaluation of the validity of LOCF. This, however, requires further research.

Logistic Regression

Rick Chappell and Jason Fine

University of Wisconsin–Madison, Madison, Wisconsin, U.S.A.

Abstract

Logistic regression is a model intended for situations in which the dependent variable Y consists of a binary (yes/no) outcome and the vector of independent variables or covariates $\mathbf{x}$, as in ordinary linear models, may either be continuous, dichotomous, or factors. The aim of this entry is to provide examples of this model to illustrate its application.

INTRODUCTION

Logistic regression is a model intended for situations in which the dependent variable Y consists of a binary (yes/no) outcome and the vector of independent variables or covariates $\mathbf{x}$, as in ordinary linear models, may either be continuous, dichotomous, or factors. Examples of binary outcomes include death/survival, toxicity/lack of toxicity, efficacy/inefficacy, and, in general, the occurrence of an event vs. otherwise. Y is typically coded as 1 if the event occurs and 0 if the event does not occur so that its mean $E(Y|\mathbf{x})$ is the probability of occurrence given covariates.

OVERVIEW

There are two reasons why the standard linear model is, in general, unsatisfactory for binary outcomes. The first is that linearity on the raw scale is unrealistic: The conditional mean of Y , $E(Y|\mathbf{x}) = \pi_{\mathbf{x}}$, is not constrained to lie between 0 and 1, whereas proportions must be so. The second is that for a binary outcome Y , $\text{Var}(Y|\mathbf{x}) = \pi_{\mathbf{x}}(1 - \pi_{\mathbf{x}})$ and so violates the usual linear model assumption of variance homogeneity across covariates.

As an example of the former, consider the example of menarche in Warsaw girls (Ref. 1, Section 7.2). Table 1 shows these data in grouped form giving for each group the total number of girls, the number who have achieved menarche, and the median age.

The proportions are plotted as dots in Fig. 1, in which dashed and solid curves give the fits of linear and logistic regressions, respectively. Note that the former exceeds 1 for ages over 16 years and becomes negative for those under 10 years, whereas the latter is mathematically prohibited from doing either. The logit function is sigmoidal or s-shaped so that the slope is tempered toward each extreme. Formally, if $\mathbf{x}_i$ is the known covariate vector for the i th subject, which in this example includes the i th girl's age, then

$$\begin{aligned}\text{logit}[E(\gamma_i | \mathbf{x}_i)] \\ &= \text{logit}[\text{Pr}(\text{menarche for subject } i \text{ given her age})] \quad (1) \\ &= \text{logit}(\pi_i) = \log[\pi_i/(1 - \pi_i)] \\ &= \beta_0 + \beta_1 \times \text{age}_i\end{aligned}$$

where β_0 and β_1 are unknown. In general, there is a vector of unknown parameters β and

$$\begin{aligned}\text{logit}[\text{Pr}(\text{event for subject } i | \mathbf{x}_i)] &= \log[\pi_i/(1 - \pi_i)] \\ &= \mathbf{x}_i^T \beta\end{aligned} \quad (2)$$

A constant term is usually included whose element of $\mathbf{x}$ is always 1. It corresponds to the intercept in a linear model and is denoted β_0 . As $\pi/(1 - \pi)$ is the odds of an event, logistic regression is a linear model on the logarithm of the odds. For two different subjects denoted i and j , their odds ratio of the event is defined as

$$\begin{aligned}\text{OR}(i, j) &= \left\{ \pi_i / (1 - \pi_i) \right\} / \left\{ \pi_j / (1 - \pi_j) \right\} \\ &= \exp\left\{ (\mathbf{x}_i - \mathbf{x}_j)^T \beta \right\}\end{aligned} \quad (3)$$

Note that because the logit function is symmetric, logistic regression is invariant to the definition of $Y = 1$ as an event or nonevent. That is, for example, one achieves the same predicted values whether “death” or “survival” is considered to be an event; odds ratios are merely inverted, parameter estimates are the same magnitude but negated, and standard errors and confidence intervals are identical under the two formulations.

Because, as mentioned above, $\pi_{\mathbf{x}}$ can be considered the conditional mean of the random variable Y , logistic regression is a member of the class of general linear models in which a function of the mean is linear in the covariates. Although we use the logit function here, others are practical and sometimes preferable for binary data. These are

MAXIMUM LIKELIHOOD ESTIMATION

By far, the most commonly used method of obtaining estimates for the coefficients β is that of maximum likelihood estimation. In this paradigm, a likelihood function of the parameters is generated for the sample in which higher values are supported by the data, and the value of β which produces the highest likelihood is the maximum likelihood estimate (MLE), often denoted as $\hat{\beta}$. Eq. 2 can be inverted with $\hat{\beta}$ substituted for β in order to produce a predicted or fitted probability for a vector of covariates $\mathbf{x}_i$:

$$\hat{\pi}_i = \frac{1}{1 + \exp(\mathbf{x}_i^T \hat{\beta})} \quad (4)$$

In addition, $\hat{\beta}$ can be substituted into Eq. 3 to produce estimated odds ratios. Various methods of inference on MLEs exist which generate tests, estimated standard errors, and confidence intervals using $\hat{\beta}$ and functions of it; see Appendix I of Cox and Snell^[3] for a detailed treatment. Almost all statistical packages give asymptotic standard errors for $\hat{\beta}$ and the resultant Wald tests for the null hypotheses that the components of β are 0. These can be unreliable when any component of $\hat{\beta}$ is large, in which case inference based on likelihood ratio statistics is preferred.^[4] A likelihood ratio test of the null hypothesis that one or more elements of β is zero is achieved by fitting both the

full model and one without the corresponding elements of $\mathbf{x}$. Twice the difference in the two log likelihoods is compared to a Chi-squared distribution with degrees of freedom equal to the number of parameters tested.

The method of iteratively reweighted least squares (IRLS) is often used to calculate MLEs (Ref. [2], Section 2.5). In IRLS, Eq. 2 is approximated by a linear model and then fitted. However, this approximation requires knowledge of β ; thus, initial values must be assumed. The fit then produces updated estimates of β which are reinserted, etc., until convergence, with the final estimate being $\hat{\beta}$. IRLS has the advantage of using well-known algorithms for least-square regression; in addition, useful diagnostics can be computed by running only one iteration of IRLS.

A limitation of inference based on unconditional maximum likelihood is its reliance on large-sample approximations. Alternative approaches based on conditional likelihoods may provide more accurate results. The idea is to condition on the sufficient statistic for the intercept in the logistic regression, which is the total number of successes; that is, the number of Y_i equaling one. Inferences about the remaining components of β may then be based on the likelihood for Y_i conditional on $\sum_i Y_i$ ^[5] and do not involve the nuisance parameter, which may cause instability with small to moderate sample sizes. An asymptotic analysis of this conditional likelihood gives distributional results for the Wald's score and likelihood ratio tests which are similar to those for the unconditional likelihood. More recently, so-called exact methods have been developed based on certain permutation distributions which give p values which are valid for all sample sizes.^[6] The methodology has been popularized in the widely used software LogXact.^[7]

Table 1 Menarche in Polish Girls (*Continued*)

Age	13.1	13.3	13.6	13.8	14.1	14.3	14.6	14.8	15.2	15.3	15.6	15.8	17.6
Total	99	106	105	117	98	97	120	102	122	111	94	114	1049
Menarche	47	67	81	88	79	90	113	95	117	107	92	112	1049

INTERPRETATION

The major disadvantage of the nonlinear form of Eq. 2 is that the resultant parameter estimates are not immediately interpretable. Returning to the menarche data of Table 1, consider the linear regression whose fit is represented by the straight line in Fig. 1. Its slope is 0.19/yr; thus, the corresponding estimated chance of reaching menarche increases by 19%/yr, an easily explainable (if obviously incorrect) figure. Logistic regression produces the estimated coefficient $\hat{\beta} = 1.63/\text{yr}$, the amount by which the logarithm of the estimated odds of menarche increases for each year a girl's age advances. This is an unintuitive result. One way in which to make it slightly less is by exponentiating it to form an odds ratio: $\exp(1.63) = 5.11$ so that we can say that adding a year multiplies the odds of menarche by this factor. We would say that 5.11 is the "estimated odds ratio of menarche with respect to age, in years."

If there were other covariates in this example besides age, we would call its exponentiated fitted coefficient the "estimated odds ratio of menarche with respect to age, in years, controlling [or adjusting] for all other factors." This is equivalent to considering two subjects in Eq. 3 for whom $\text{age}_i - \text{age}_j = 1$, but whose other elements of $\mathbf{x}$ are the same.

Finally, one can be dissatisfied with odds ratios because they are not otherwise commonly used in medical discourse in preference for percentages.^[8] Although an exact conversion cannot be made because the logistic model is not linear in percentages, useful approximations do exist. For example, the steepest slope always occurs at the median (about 13 years in Fig. 1) and is computed by multiplying the estimated coefficient by a factor of 25. Thus, for 13 year olds, the percentage of girls reaching menarche increases by $25 \times 1.63 = 41\%/\text{yr}$. The general factor for approximate conversion to linearity is

$$\text{conversion factor} = 100\% \times p \times (1 - p) \quad (5)$$

where p is some relevant proportion (here 0.5, but often, the overall sample proportion of events).

GOODNESS-OF-FIT DIAGNOSTICS

The practical utility of the logistic model is its ability to estimate summary risks for covariates taking a wide range of values. The most appropriate interpretation of the results involves the interpolation of the model over the range of the

covariates used in the model fitting. The common wisdom is that extrapolation may give misleading results, which are driven by modeling assumptions which cannot be verified with the observed data. Of course, model misspecification is also important when interpolating and is often ignored. For this scenario, a variety of techniques are available for model assessment and should be used whenever possible.

In linear regression, the building block for model diagnosis is the residual, i.e., the difference between the observed response and its expected value under the assumed model. Plotting the fitted residuals vs. the covariates may indicate lack of fit when the residuals show systematic deviation from zero. In certain cases, the functional forms of covariates may be identifiable from the plots. Because logistic regression is inherently nonlinear and the binary response is highly discrete with an asymmetric, skewed distribution, these nice properties do not carry over to an analogously defined residual from the logistic regression model. Such scatterplots are notoriously uninformative. However, displaying the results of a nonparametric regression of the residuals on a covariate overlaid on the plot may reveal nonlinearities, which suggest alternative forms of the covariate.

The so-called Pearson residuals, the raw residuals divided by standard error estimates, may be used to construct Pearson-type tests^[9,10] which may be helpful in assessing overall goodness of fit. Unfortunately, such tests may require an arbitrary partitioning of the covariate space which may be unattractive with continuous covariates. In addition, the tests may not be helpful for evaluating individual covariates. A simple approach to this problem is to include other forms of the covariate to check the fit of the form under consideration. For example, with scalar $\mathbf{x}_i$, one may diagnose the appropriateness of the covariate form by fitting a model with $\mathbf{x}_i$ and $\mathbf{x}_i^2$ and evaluating the significance of $\mathbf{x}_i^2$.

To further explore misspecification of the covariates, one may employ the generalized additive model.^[11] In this formulation, $\mathbf{x}_i^T \boldsymbol{\beta}$ is replaced by a sum of unknown functions of $\mathbf{x}_i$ in the logistic model. Here the functions denote the individual covariate effects. If the simple logistic model is correctly specified, then for component j of $\mathbf{x}_i$, say, x_{ij} , the corresponding function is $x_{ij}\beta_j$, where β_j is component j of $\boldsymbol{\beta}$. The estimated functions may be plotted and evaluated visually for departures from linearity. These plots are generally quite useful and may suggest other forms of the covariates. Formal tests for the functional forms of the covariates have not been well studied using this technique.

In some cases, the logistic function relating the binary probability to the covariates may be invalid. To determine whether this is the case, specialized tests^[12] may be used. Alternatively, one may fit a model with a flexible link function involving additional parameters which are simultaneously estimated with the covariate effects using maximum likelihood. This is the approach advocated by Stukel,^[13] where a number of link classes are compared and contrasted, each containing the logistic model as a special case. In practice, it may be difficult to estimate the link parameter well, except in large samples. The menarche example of Table 1 may be such a case. Taylor^[14] has examined the variance inflation for the covariate effects associated with estimating the link parameter when it is known. In general, the cost decreases as the number of covariates in the model increases.

Outlying observations and influential points are common problems in linear regression. Pearson residuals are helpful in identifying outliers, and leverages derived from the hat matrix may provide insight into the influence of individual observations. These techniques are not easily adapted to logistic regression. Alternative procedures based on score and deviance residuals are discussed in Williams^[15] and Davison and Tsai;^[16] they are broadly applicable to assessing generalized linear models.

EXAMPLE: THE BRITISH INSTITUTE OF RADIOLOGY TRIALS OF RADIOTHERAPY IN CANCER OF THE LARYNX AND THE PHARYNX

The British Institute of Radiology (BIR)^[17,18] conducted two large-scale randomized clinical trials to assess the effectiveness of different treatment radiotherapeutic schedules for cancer of the larynx and the pharynx. For the purposes of this analysis, the studies' results are merged; unlike the primary analyses, which were simple comparisons based upon the randomization, we will here model patient outcome as a function of the treatment characteristics in order to gain insight into the underlying radiobiological mechanisms. The event here is a 3-year

local control. There are four components of the covariate vector $\mathbf{x}$: D , the total dose in grays (Gy); DD/f , the “fractionation factor” in square Gy which is large when treatment is administered in many separate increments and small otherwise; t , the total time of treatment in days; and stage, a three-level covariate which represents increasing invasiveness of the tumor (which, as a factor, is coded as two 0/1 elements in $\mathbf{x}$ using stage I as the baseline for comparison). The elements of β corresponding to these predictive factors are β_D , $\beta_{DD/f}$, β_t , and β_{stage} along with the usual constant term β_0 . We fit this model using information from the 858 usable laryngeal cancer patients with negative nodal and metastatic status in both studies, of whom 590 had 3-year local control. See the references cited above for further details, theoretical justification of the model, and analyses.

Table 2 gives MLEs for the BIR data using the logistic model and covariates described above. Although these results do not yield any surprises, they bear commentary and interpretation (as always in any scientific presentation). We compute and display $\hat{\beta}_0$ because of its use for computing fitted values in Eq. 4; however, a p value for the constant term is almost never relevant and should not be stated. For the other covariates, the “Percentage scale” column shows the approximate effects on the 100% $\times$ probability scale. These were obtained by substituting the proportion of events $p = 590/858 = 0.69$ into Eq. 5 to get a conversion factor of 21.5%. Thus, $\hat{\beta}_D = 0.05912$ was multiplied by $100\% \times 0.215$ to get an approximate change per Gy on the raw scale of 1.3%. This implies that each Gy of total dose increases local tumor control by 1.3%; an extra 10 Gy increases control rates by 13%; etc. (here and below, the calculations assume that all other covariates are held constant). A delay of 10 days would decrease local control by nearly 9%. The fractionation factor DD/f is not very important either in terms of the clinical significance of $\hat{\beta}_{DD/f}$ or its p value. The effects of tumor stage are large and in the expected direction; thus, the estimated local control among patients with stage II and stage III is 15% and 22% lower than in patients with stage I invasive tumors, respectively. All these effects are plotted in Fig. 2.

Table 2 Estimated Logistic Regression Model for the BIR Data

Variable	Coefficient estimate	Standard error	p Value	Percentage scale
Constant	−0.937	0.979		
D	0.0591/Gy	0.0186	0.002	1.4%/Gy
DD/f	0.00221/Gy ²	0.00285	0.4	0.047%/Gy ²
t	−0.0419/day	0.0124	0.0007	−0.89%/day
Stage II	−0.711	0.188	<0.001	−15%
Stage III	−1.044	0.187	<0.001	−22%

Fig. 2 A graphical display of the coefficients in Table 2

Alternatively, and more commonly, the coefficients can be exponentiated to form odds ratios. The odds ratio of local control with respect to total dose is $\exp^{0.0591} = 1.061/\text{Gy}$; the odds ratio of control with respect to time is 0.96/day or 0.66 per 10 days; the odds ratio of control with respect to stage II vs. I is 0.49; and with respect to stage III vs. I, it is down to 0.35. As before, these should be interpreted as the estimated effects after controlling for all other predictors in the model.

These results also directly address other interesting clinical questions. For example, some patients in the second study received 50 Gy in 16 fractions over 3 weeks and others received 63 Gy in 31 fractions over 6 weeks. If both such patients had stage I tumors, we can substitute ($D = 50$ Gy, $DD/f = 156.3$ Gy², $t = 21$ days) and ($D = 63$ Gy, $DD/f = 128$ Gy², $t = 42$ days) into Eq. 4 using the estimated coefficients in Table 2 to yield the estimated local control percentages of 82% and 79%. These give an estimated odds ratio of 1.19 although we can use Eq. 3 as a shortcut

$$\begin{aligned} & \log[\widehat{\text{OR}}(50\text{Gy}/156.3\text{Gy}^2/21\text{days}, \\ & \quad 63\text{Gy}/128\text{Gy}^2/42\text{days})] \\ &= \hat{\beta}_D(50 - 63) + \hat{\beta}_{DD/f}(156.3 - 128) + \hat{\beta}_t(21 - 42) \end{aligned} \quad (6)$$

resulting in the same answer. This formulation has the advantage of making it simple to compute an estimated variance of the log odds ratio:

$$\begin{aligned} & \widehat{\text{Var}}[\log[\widehat{\text{OR}}(50\text{Gy}/156.3\text{Gy}^2/21\text{days}, \\ & \quad 63\text{Gy}/128\text{Gy}^2/42\text{days})]] \\ &= \widehat{\text{Var}}(\hat{\beta}_D) \times (50 - 63)^2 + \widehat{\text{Var}}(\hat{\beta}_{DD/f}) \\ & \quad \times (156.3 - 128)^2 + \widehat{\text{Var}}(\hat{\beta}_t) \times (21 - 42)^2 \\ & \quad + \widehat{\text{Cov}}(\hat{\beta}_D, \hat{\beta}_{DD/f}) \times (50 - 63) \times (156.3 - 128) \\ & \quad + \widehat{\text{Cov}}(\hat{\beta}_D, \hat{\beta}_t) \times (50 - 63) \times (21 - 42) \\ & \quad + \widehat{\text{Cov}}(\hat{\beta}_{DD/f}, \hat{\beta}_t) \times (156.3 - 128) \times (21 - 42) \end{aligned} \quad (7)$$

where the estimated variances and covariances are the relevant elements of the asymptotic covariance matrix (inverted Fisher information matrix) calculated by most logistic regression programs. One uses this to compute a confidence interval for the log OR which is then exponentiated to create a confidence interval for the OR of (0.83, 1.71). Therefore, the evidence cannot discriminate between the two regimens.

Finally, one can also depict these results by computing the fitted probabilities using Eq. 4 and plotting them. This is done in one dimension by varying a single predictor while holding the others fixed, or in two dimensions by varying two predictors. Fig. 3 shows the estimated probabilities of local control at 3 years for a range of total doses and times. For this purpose, tumor stage was set at I and the number of fractions f was fixed at 19 (this was thought to yield a more interpretable plot in this case

Fig. 3 Probability of local control at 3 years vs. dose and treatment time; 19 fractions, stage I

than just setting $DDIf$ to a constant value as could also be done). Fig. 3 shows how the estimated response surface of tumor control probability changes dramatically with time and dose.

Abstract

This article focuses on logistic regression process for model building, its validation, and its generalizability in case-control studies. The process includes determination of associations between potential risk factors and clinical outcomes, identification of risk factors for medical predictive model building, and internal/external validation of the established predictive model. The process starts with propensity score matching between the case and control groups followed by (i) descriptive analysis to have better understanding of the data, (ii) univariate analysis to test associations between the risk factors (or predictors) and the clinical outcomes (e.g., safety and efficacy), (iii) collinearity analysis to test associations/correlations between predictors (explanatory variables or risk factors), (iv) multivariate analysis to test the association of a predictor after adjusting for other predictors or potential confounders, and (v) model diagnostic/validation to determine the goodness of fit of the final model.

Keywords: Clinical research; Generalizability; Logistic regression process; Model validation; Predictive model building.

INTRODUCTION

In clinical research, case-control studies utilizing the existing database are commonly considered. A case-control study typically consists of two existing groups of patients, i.e., the group of cases and the group of control, which are identified and compared on the basis of some predetermined causal attributes. In practice, case-control studies are often conducted to identify the factors that may contribute to a medical condition by comparing subjects who have that condition and/or disease. These subjects are referred to as *cases*. Those subjects who do not have the condition and/or disease but have similar characteristics are considered as the *controls*. One of the most significant examples of the case-control study was the demonstration of the link between tobacco smoking and lung cancer.^[1] They found a statistically significant association between smoking and lung cancer in a large case-control study. The results, which were obtained based on nonrandomized, epidemiological observational studies rather than randomized trials, have been criticized in that this type of study cannot prove causation, but do confirm the causal link between smoking and lung cancer.

The primary objective of case-control studies is not only to study the relationship between clinical outcomes (e.g., safety and efficacy) and possible risk factors (e.g., demographics and patient characteristics), but also to develop a medical predictive model based on the identified risk factors. In recent years, it is also of particular interest to examine the generalizability of the established predictive model (e.g., from one patient population such as adults to another similar but different patient population such as pediatrics or from one medical center to another). For this purpose, multivariate (logistic) regression process is probably the most commonly used method. The use of logistic regression analysis for identifying potential risk factors (or predictors) in order to build a predictive model has become very popular in clinical research.^[2]

In practice, for a given database, the process of logistics regression analysis for model building in case-control studies starts with propensity score matching between the case and control groups followed by (i) descriptive analysis to have better understanding of the data, (ii) univariate analysis to test associations between the risk factors (or predictors) and the clinical outcomes (e.g., safety and efficacy), (iii) collinearity analysis to test associations/

correlations between predictors (explanatory variables or risk factors), (iv) multivariate analysis to test the association of a predictor after adjusting for other predictors or potential confounders, and (v) model diagnostic/validation to determine the goodness of fit of the final model. This step is usually considered as an internal validation. In addition, one may consider testing generalizability of the established medical predictive model from either one patient population (e.g., adults or elderly) to another similar but different patient population (e.g., pediatrics) or one medical center to another in different geographical location. Steps (i)–(iii) are usually implemented by the univariate logistic regression and steps (iv)–(v) are by the multiple logistic regression analysis. In this entry, the process of logistics regression analysis for model building including its generalizability is described.

PROPENSITY SCORE MATCHING

In clinical research, one of the major concerns of a case–control study is selection bias, which is often caused by a significant difference or imbalance between the case and control groups, especially for large observational studies.^[3–5] In this case, the target patient population under study in the control group may not be comparable to that in the case group. This selection bias could alter the conclusion of the treatment effect due to possible confounding effects. Consequently, the conclusion may be biased and hence misleading.

An example regarding the impact of imbalance between the case and control groups (e.g., in ethnic factors on the responses to therapeutics) is the epidermal growth factor receptor (EGFR) tyrosine kinase inhibitor gefitinib (Iressa). Recently, Iressa was approved in Japan and the United States for the treatment of non-small-cell lung cancer (NSCLC). The EGFR is a promising target anticancer therapy because it is more abundantly expressed in lung carcinoma tissue than in adjacent normal lung tissue. However, clinical trials have revealed a significant variability in the response to gefitinib with higher responses observed in Japanese patients than in a predominantly European-derived population (27.5% vs. 10.4%, in a multi-institutional phase II trial^[6]). Paez et al.^[7] also show that somatic mutations of the EGFR were found in 15 of 58 unselected tumors from Japan and 1 of 61 from the United States. Treatment with Iressa causes tumor regression in some patients with NSCLC, more frequently in Japan. Finally, the striking differences in the frequency of EGFR mutation and the response to Iressa between Japanese and American patients raise general questions regarding variations in the molecular pathogenesis of cancer in different ethnic, cultural, and geographic groups. Recently, generalibility of a new treatment has attracted more and more attention from sponsors as well as regulatory authorities; the key issues

such as when and how to address the geographic variations of efficacy and safety for the statistical inference are still some challenges.

To overcome this problem, Rosenbaum and Rubin^[3] proposed the concept of *propensity score* as a method to reduce the selection bias in observational studies. Propensity score is a conditional probability (or score) of the subject being in a particular group when given chosen characteristics. The use of propensity score helps to match the case and control groups based on baseline characteristics as in a randomized experiment for reducing bias. In other words, using propensity score enables the assessment of the treatment effects more reliably. Consider the case group as those who received a certain treatment ($T = 1$) and the control group as those who did not receive this treatment ($T = 0$). Let X be a vector that represents baseline demographics and/or patient characteristics that are important (e.g., possible confounding factors) for matching the case and control populations for reducing the selection bias. The propensity score is then given by

$$p(X) = \Pr[T = 1 | X] = E(T | X)$$

where $0 < p(X) < 1$. The exclusion of $p(X)$ extreme values such as 0 and 1 indicates that every subject has a nonzero change of being in the case or the control group. This condition is part of the assumption that treatment assignment should be strongly ignorable. Propensity score matching is a powerful tool reducing the bias due to possible confounding effects. Sometimes, propensity score matching is also considered as *post-study* randomization compared to a randomized clinical trial for reducing the bias.

In practice, several methods can be applied to build a propensity score model. One of the commonly used approaches is probably the *logistic regression* for binary outcomes, i.e., $T = 1$ for the case group and $T = 0$ for the control group. The propensity score $p(X)$ can be estimated based on the logistic regression model, where $p(X)$ is the conditional probability of being assigned to the case group given covariates X : $p(X) = \Pr[T = 1 | X]$. The natural log odds ratio of $p(X)$ equals a linear function of covariates X , and $p(X)$ is assumed to be between 0 and 1. This linear combination of X indicates that every increment of a component of x would add or subtract so much to the final conditional probability $p(X)$.

$$\begin{aligned} \text{logit}(p(X)) &= \log\left(\frac{p(X)}{1 - p(X)}\right) \\ &= \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_n X_n = X^T \beta \end{aligned} \quad (1)$$

where X is the covariate matrix: $X = [1, X_1, X_2, \dots, X_n]^T$, and β is the coefficient matrix, which is given by $\beta = [\beta_0, \beta_1, \beta_2, \dots, \beta_n]^T$. Then, the propensity score $p(X)$ can be solved as follows:

$$p(X) = \frac{e^{x^T \beta}}{1 + e^{x^T \beta}} = \frac{1}{1 + e^{-x^T \beta}} \quad (2)$$

It should be noted that for propensity score matching, data available for matching will decrease as the number of matching factors (potential confounding factors) increases.

MODEL BUILDING

Model building involves univariate analysis for identifying risk factors (or predictors) and multivariate analysis or possible collinearity, which are critical for establishing an accurate and reliable predictive model and will be briefly described subsequently.

Univariate Analysis

Let Y be the outcome variable, which could be a discrete response variable, e.g., a binary response variable where $Y = 1$ if it is a success and $Y = 0$ if it is a failure or a categorical variable where $Y = 1$ if there is an improvement, $Y = 0$ where there is no change, or $Y = -1$ when the symptom has worsened. Also, let X be any type of covariate (e.g., continuous or dichotomous). For simplicity, consider a cirrhotic study. The 6-month survival of cirrhotic patients, X could be TCR functional status, TCR marked muscle wasting and serum creatinine, or demographics characteristics that could be potential risk factors (predictors) such as gender, age, or weight. Considering univariate logistic regression, the general model with on covariate is given by

$$\text{logit}(\pi) = \log\left(\frac{\pi}{1-\pi}\right) = \alpha + \beta x \quad (3)$$

where π is the probability of success at a covariate level x . The logistic regression model can be rewritten as

$$\frac{\pi}{1-\pi} = e^{\alpha + \beta x} = e^{\alpha} \{e^{\beta}\}^x$$

where e^{β} represents the change in the log odds of the outcome by increasing x by one unit. In other words, every one unit increase in x increases the odds by a factor of e^{β} . More specifically, if $\beta = 0$ (i.e., $e^{\beta} = 1$), then the probability of success is the same at each level of x . When $\beta > 0$ (i.e., $e^{\beta} > 1$), the probability of success increases as x increases. Similarly, when $\beta < 0$ (i.e., $e^{\beta} < 1$), the probability of success decreases as x increases. To test the significance of the single variable model for the null hypothesis, $\beta = 0$, one can use the Wald test statistic^[8]:

$$Z = \frac{\hat{\beta}}{SE(\hat{\beta})}$$

where $\hat{\beta}$ is the coefficient estimate of x and $SE(\hat{\beta})$ is the standard error of $\hat{\beta}$. Z follows the standard normal distribution with mean 0 and standard deviation 1. The null hypothesis will be rejected when $Z > Z_{1-\alpha/2}$ for a two-sided test at α level. Similarly, the log-likelihood test can also be used to determine whether x is a significant predictor of Y . Under the null hypothesis that $H_0: \beta = 0$, the log-likelihood test is given by

$$G = -2 \ln \left(\frac{\text{Likelihood without the variable}}{\text{Likelihood with the variable}} \right)$$

where G follows a chi-square distribution with 1 degree of freedom.^[8] The null hypothesis will be rejected when $G > \chi^2(1)$ for a two-sided test at α level.

Test for Collinearity

As indicated by Belsley et al.,^[9] two varieties are collinear if the data vectors representing them lie on the same line. Generally, k varieties are collinear when the vectors that represent them lie in a subspace of dimension less than k , or if one of the vectors is a linear combination of the others. Since collinear varieties do not provide information that is significantly different from the information provided by the other variables included, it would be difficult to make inference on the relationship between the covariates and the outcome. Therefore, a collinearity analysis between each pair of the predictors is necessary before building a multivariate model.

To test collinearity between quantitative variables, the Pearson correlation coefficient between independent predictors can be checked. The correlation coefficient between two variables (X_1, X_2) can be calculated as follows:

$$\rho_{X_1, X_2} = \frac{\text{cov}(X_1, X_2)}{\sigma_{X_1} \sigma_{X_2}}$$

where $\text{cov}(X_1, X_2)$ is the covariance between X_1 and X_2 , σ_{X_1} is the standard deviation of X_1 , and σ_{X_2} is the standard deviation of X_2 . For binomial or multinomial variables, the chi-square test can be used to check collinearity issues. The variance inflation factors (VIFs) can also be used for further measuring the collinearity in a multiple regression model, and it is defined as follows:

$$\text{VIF}_j = \frac{1}{1 - R_j^2}, \quad j = 1, 2, 3, \dots, k$$

where R_j^2 is the squared multiple correlation based on regression X_j on the remaining $k - 1$ predictors.^[9] That is, $R_j^2 = R_{X_j|X_1, X_2, \dots, X_{j-1}, X_{j+1}, \dots, X_k}^2$. The larger the value of VIF, the more signal of collinearity will be between the independent predictors.

Once the highly correlated covariates are identified, decisions will be made regarding the variables that should be excluded from the next modeling building step. The variables to be included in the modeling building step should also have clinical significance. The reason is that removing some highly correlated variables will not only simplify the model built but also make the estimates of covariates more precise.

Multivariate Analysis

Similarly, the general logistic regression model with multiple covariates can be written as follows:

$$\log\left(\frac{\pi}{1-\pi}\right) = \alpha + \beta_1 x_1 + \beta_2 x_2 + \dots + \beta_k x_k \quad (4)$$

where log odds are a linear function of the covariates. To assess the significance of the model, the likelihood ratio test can be performed in the same way as described for the univariate testing step. The null hypothesis for the multivariable model is $H_0: \beta_1 = \beta_2 = \beta_3 = \dots = \beta_k = 0$, and the alternative hypothesis is that at least one of the coefficients is not equal to zero. The test is given by

$$G = -2\ln\left(\frac{\text{Likelihood of the null model}}{\text{Likelihood of the full model}}\right)$$

The null hypothesis would be rejected for the two-sided test when $G > \chi^2_{\alpha/2}(k)$ at α level or when the p -value of the test is smaller than α (Hosmer and Lemeshow, 2013). To identify the significant risk factors, the Wald test should be performed for each predictor. The null hypothesis is $\beta_j = 0$, where $j \in 1, 2, \dots, k$, and the Wald test statistic is calculated as follows:

$$Z_j = \frac{\hat{\beta}_j}{SE(\hat{\beta}_j)}$$

where $\hat{\beta}_j$ is the coefficient estimate of x_j and $SE(\hat{\beta}_j)$ is the standard error of $\hat{\beta}_j$. Z follows a standard normal distribution with mean 0 and standard deviation 1. The null hypothesis will be rejected when $Z > Z_{1-\alpha/2}$ for a two-sided test at α level.

Model Selection

For model building, selection of an efficient subset of the explanatory variables or predictors that account for maximum variability in the outcome is the ultimate goal of the multiple logistic analysis. In practice, three model selection procedures commonly used are forward, backward, and stepwise processes. Forward selection procedure starts with an empty model and iteratively adds variables into the model one at a time. The variables added to the

model are those that can minimize the criterion mentioned previously. On the other hand, backward selection procedure starts with a full model and removes the least significant variable step by step. After fitting the model with all variables, the best model can be selected based on either the Akaike information criteria (AIC) or the Bayesian information criteria (BIC) given as follows:

$$\begin{aligned} \text{AIC} &= -2\log L(\hat{\pi}, y) + 2p \\ \text{BIC} &= -2\log L(\hat{\pi}, y) + 2p\ln(n) \end{aligned}$$

where p is the number of variables in the model of interest and n is the number of observations in the data.^[10] Both AIC and BIC add penalty to the criteria, and we can see from the definition that BIC has more penalty added compared to AIC. As a result, BIC tends to select a model with fewer variables compared to the model selected using AIC.

Model Diagnosis and Internal Validation

The developed model can then be tested for goodness of fit, which can serve as the diagnostic tool for model selection. Commonly considered goodness-of-fit tests include (i) Pearson goodness-of-fit test, (ii) deviance goodness-of-fit test, (iii) Hosmer and Lemeshow goodness-of-fit test (only for binomial outcome), (iv) pseudo R -square, (v) pseudo adjusted R -square, and (vi) score test for assumption of proportional odds (only for ordinal outcome). Detailed information regarding these tests can be found in the work of Hosmer and Lemeshow.^[2]

For the validation of the final model, an internal validation of the developed model is usually performed, whereas an external validation for assessment of its generalizability is often performed. In practice, a commonly considered procedure for model validation is to randomly split the data set into two sub-data sets: one contains 90% of the data and the other one contains 10% of the data. The data set that contains 90% of the data is usually referred to as *training* data set, which is used to build up the predictive model based on the identified possible risk factors (predictors). As indicated earlier, the commonly considered criterion for model selection is the so-called information criterion such as AIC, BIC, or Schwartz criteria. The second data set that contains 10% of the data is known as the *validation* data set, which is used to validate the selected final model. If the closeness of the predictive values and the observed responses is within a prespecified range, we claim that the model is validated.

MODEL GENERALIZABILITY

In clinical research, it is often of interest to generalize clinical results obtained from a given target patient population at a medical center to a similar patient population at another medical center. Thus, model generalizability is

also referred to as external validation as the established model is validated based on a similar but different database obtained either from a similar but different patient population (e.g., elderly patient population) or from a different medical research center. Denote the original target patient population by (μ_0, σ_0) and the similar but different patient population by (μ_1, σ_1) . Since the two populations are similar but different, it is reasonable to assume that $\mu_1 = \mu_0 + \varepsilon$ and $\sigma_1 = C\sigma_0$ ($C > 0$), where ε is referred to as the shift in location parameter (population mean) and C is the inflation factor of the scale parameter (population standard deviation). Thus, the (treatment) effect size adjusted for the standard deviation of population (μ_1, σ_1) can be expressed as follows:

$$E_1 = \frac{\left| \frac{\mu_1}{\sigma_1} \right|}{\left| \frac{\mu_0}{\sigma_0} \right|} = \frac{\left| \frac{\mu_0 + \varepsilon}{C\sigma_0} \right|}{\left| \frac{\mu_0}{\sigma_0} \right|} = |\Delta| \frac{\left| \frac{\mu_0}{\sigma_0} \right|}{\left| \frac{\mu_0}{\sigma_0} \right|} = |\Delta| E_0 \quad (5)$$

where $\Delta = (1 + \varepsilon/(\mu_0)/C)$, and E_0 and E_1 are the effect sizes (of clinically meaningful importance) of the original target patient population and the similar but different patient population, respectively. Chow et al.^[11] and Chow and Chang^[12] refer Δ as a sensitivity index measuring the change in the effect size between patient populations. As it can be seen from the above, if $\varepsilon = 0$ and $C = 1$ (there is no shift in the target patient population; the two patient populations are identical), $E_1 = E_0$. That is, the effect sizes of the two populations are identical. In this case, we claim that the results observed from the original target patient population (e.g., adults) can be generalized to the similar but different patient populations. Thus, if we can show that the sensitivity index Δ is within an acceptable range, say 80% and 120%, we may claim that the results observed at the original medical center can be generalized to another medical center with the similar but different patient populations.

As indicated in Chow et al.,^[13] the effect sizes of the two populations could be linked by baseline demographics or patient characteristics if there is a relationship between the effect sizes and the baseline demographics and/or patient characteristics (a covariate vector). However, such covariates may not exist or may not be observable in practice. In this case, Chow et al.^[13] suggested assessing the sensitivity index by simply replacing ε and C with their corresponding estimates. Intuitively, ε and C can be estimated by

$$\hat{\varepsilon} = \hat{\mu}_1 - \hat{\mu}_0 \text{ and } C = \hat{\sigma}_1 / \hat{\sigma}_0$$

where $(\hat{\mu}_0, \hat{\sigma}_0)$ and $(\hat{\mu}_1, \hat{\sigma}_1)$ are some estimates of (μ_0, σ_0) and (μ_1, σ_1) , respectively. Thus, the sensitivity index can be estimated by

$$\hat{\Delta} = \frac{1 + \hat{\varepsilon} / \hat{\mu}_0}{\hat{C}} \quad (6)$$

Note that in practice, the shift in location parameter (i.e., ε) and/or the change in scale parameter (i.e., C) could be random. If both ε and C are fixed, the sensitivity can be assessed based on the sample means and sample variances obtained from the two populations. In real-world problems, however, ε and C could be either a fixed or a random variable. In other words, there are three possible scenarios: (i) the case where ε is random and C is fixed, (ii) the case where ε is fixed and C is random, and (iii) the case where both ε and C are random. These possible scenarios have been studied by Luet al.^[14]

CONCLUDING REMARKS

Logistic regression analysis is useful in determining/identifying the risk factors (predictors) for building the medical predictive model in case-control studies. Goodness of fit and internal validation are necessarily performed to ensure the predictability of the established medical predictive model. In addition, the assessment of generalizability of the established medical predictive model from one patient population to another and/or from one medical center to another is encouraged. In case-control studies, however, it is always a major challenge to the principal investigator when there are significant differences (or imbalances) in demographics and/or patient characteristics, which may cause confounding effects. Consequently, the results may be biased and hence misleading. In addition, the imbalances could have a negative impact on the generalizability of the clinical results. To avoid possible confounding effects due to imbalances between the case and control groups, the use of propensity score is recommended.

Logistic Regression: Three-Point Designs

Mårten Vågerö

Stockholm University, Stockholm, Sweden

Abstract

This entry discusses the problem and practical implications of infinite parameter estimates in a three-point univariate logistic regression.

INTRODUCTION

Three-point designs are frequently used in phase II clinical studies to establish a dose–response relationship before proceeding to larger confirmatory studies. In cases with a binary outcome, a logistic regression model is often adopted. As these studies are most often of small or moderate size with little prior knowledge about the effective dose interval, there is a substantial risk for an outcome with nonunique or infinite parameter estimates.

Morgan's book^[1] discusses both sequential and fixed-point designs for estimation of a particular characteristic or the entire distribution of a dose–tolerance threshold model for quantal response data. In a threshold model, each individual in the target population has a dose tolerance (threshold) to the exposure of a drug. If a subject (patient, healthy volunteer, or animal) is administered a dose above its threshold, it will respond. Otherwise, it will be a nonresponder. If subjects are assumed to be randomly sampled from a logistic tolerance threshold distribution, the probability of responding when administered a dose x can be written as

$$P(x; \mu, \beta) = \frac{e^{\beta(x-\mu)}}{1 + e^{\beta(x-\mu)}} \quad (1)$$

where μ is the median (ED_{50}) and β represents the steepness of the dose–response curve. Parameter estimates that are asymptotically unbiased, and asymptotic standard errors for these estimates, can be determined by the method of maximum likelihood through many available statistical computer packages.

However, in small sample studies, problems with infinite parameter estimates as a result of a complete or quasi-complete separation of the data may occur (see below).^[2] These situations also cause problems when working with some statistical computer packages. Certainly, there are textbooks discussing this problem,^[3] but many modern textbooks on logistic regression do not mention it at all.^[4]

A published example where this was not properly addressed is discussed in Ref. [5]. In simple studies, it is easily seen if there is a complete or quasi-complete separation of the data leading to an infinite parameter estimate. However, in more complex models with several explanatory variables, it need not be obvious from inspection of the outcome whether some parameter estimate is infinite or not. This paper will discuss the problem and practical implications of infinite parameter estimates in a three-point univariate logistic regression.

MAXIMUM LIKELIHOOD ANALYSIS

With the notation

n_i = the number of subjects who are administered the dose x_i , and
 y_i = the number of subjects responding to dose x_i , the log-likelihood derived from Eq. 1 is

$$L(\mu, \beta) = \sum_i y_i \beta (x_i - \mu) + \sum_i n_i \log \{1 - P(x_i; \mu, \beta)\} + \text{constant} \quad (2)$$

The maximum likelihood estimator (MLE) $(\hat{\mu}, \hat{\beta})$ is determined by maximizing Eq. 2. The second derivatives form the observed information matrix, here denoted $J(\mu, \beta)$. We have

$$J(\hat{\mu}, \hat{\beta}) = \begin{bmatrix} \hat{\beta}^2 \sum_i n_i \hat{P}_i (1 - \hat{P}_i) & -\hat{\beta} \sum_i (x_i - \hat{\mu}) n_i \hat{P}_i (1 - \hat{P}_i) \\ -\hat{\beta} \sum_i (x_i - \hat{\mu}) n_i \hat{P}_i (1 - \hat{P}_i) & \sum_i (x_i - \hat{\mu})^2 n_i \hat{P}_i (1 - \hat{P}_i) \end{bmatrix} \quad (3)$$

where $\hat{P}_i = P(x_i; \hat{\mu}, \hat{\beta})$.

The variance–covariance matrix of the maximum likelihood estimator (MLE) is estimated by the inverse $J^{-1}(\hat{\mu}, \hat{\beta})$ of the observed information matrix in the maximum likelihood point. We will use superscripts to denote the elements of J^{-1} , e.g., j^{11} for its upper left corner. The expected Fisher information, i.e., the expected value of J over the possible outcomes of data, will be denoted as $I(\mu, \beta)$.

CHOICE OF DESIGN POINTS

Fixed-point designs usually divide the total number of subjects equally between all dose levels. The dose levels are ideally chosen symmetrically around the center μ of the tolerance distribution and with an equal distance between the dose levels. See, for example, Ref. [6] or [1] for more details on design considerations for quantal response data. Consider now a three-point design, with $3n$ subjects equally divided between the three doses, $x_1 < x_2 < x_3$. The middle dose, x_2 , is assumed located in the center μ of the tolerance threshold distribution, and the other two doses, x_1 and x_3 , symmetrically around x_2 , say at $x_2 \pm \delta$. This makes $P_2 = 1/2$ and $P_3 = 1 - P_1$, and the expected Fisher information, $I(\mu, \beta)$, is diagonal; thus $\hat{\mu}$ and $\hat{\beta}$ are approximately uncorrelated.

$$I(\mu, \beta) = n \begin{bmatrix} \beta^2(2P_1(1-P_1)+1/4) & 0 \\ 0 & 2P_1(1-P_1)\delta^2 \end{bmatrix} \quad (4)$$

Many different optimality criteria are found in the literature. Most criteria are based on the information matrix and aim at minimizing elements or functions of the elements in the inverse information. To achieve a μ -optimal design, I^{11} should be minimized, or the equivalent $P_1(1-P_1)$ maximized; thus the design points should be chosen close to μ . An optimal design for estimating β should instead minimize I^{22} ; that is, maximize $P_1(1-P_1)\delta^2$. Using this optimality criteria, the spacing δ should be chosen so that $\delta = 2.4\beta$ or equivalent so that $P_1 = 1 - P_3 = 0.083$. A widely used optimality criterion is D-optimality, where the determinant of I is maximized.^[7] This is a design with a good balance between a low risk of a separation in data and providing an informative dose–response relation. Using the D-optimality criteria, the design points are chosen so that $P_1 = 1 - P_3 = 0.136$ or equivalently so that $\delta = 1.85\beta$.

DATA CONFIGURATIONS

In a binary dose–response model (with a single dose or a dose vector), some degenerate types of data configurations yield infinite and/or nonunique parameter estimates. Essentially, following Albert and Anderson,^[2] we characterize the sample outcomes as follows:

1. Only one response type represented in data.
2. A complete separation of responders from nonresponders.
3. A quasi-complete separation of responders from nonresponders.
4. An overlap of the two response types.

These authors^[2] discuss the problem of existence, finiteness, and uniqueness of maximum likelihood estimates in the case of several explanatory variables. A further discussion of how to interpret and handle infinite parameter estimates in a general logistic regression model is found in Ref. [8]. Next we describe what Albert and Anderson's results imply in our case with only one explanatory variable; that is, the dose.

Only One Response Type Represented in Data

The first situation is when the outcome consists of only responders or only nonresponders. The only information provided by data in this trivial case is that the design points were chosen outside the effective dose range for the specific drug under investigation. The experiment must be supplemented with more design points in the direction of the effective dose range.

A Complete Separation of Responders from Nonresponders

A complete separation means that there is a specific (but nonunique) dose level so that all responders are found at higher doses than the nonresponders (or vice versa).

Thus

$$\min_i(x_i|y_i > 0) > \max_i(x_i|y_i < n_i)$$

The probability is particularly high for obtaining such data when the dose–response curve steeply rises from ≈ 0 to ≈ 1 somewhere between $\max(x_i|y_i < n_i)$ and $\min(x_i|y_i > 0)$. It is easily verified that the maximum likelihood estimates are degenerated, being

$$\hat{\beta} = +\infty$$

and

$$\max_i(x_i|y_i < n_i) < \hat{\mu} < \min_i(x_i|y_i > 0)$$

A Quasi-Complete Separation of Responders from Nonresponders

A quasi-complete separation of responders from nonresponders means that there is a unique dose level x^* in the design such that all responders occur at $x_i \geq x^*$, and all nonresponders occur at dose levels $x_i \leq x^*$ (or vice versa), with both responders and nonresponders at x^* .

In this situation, the highest probability for the observed data is obtained if the dose–response curve steeply rises at the particular dose x^* . Hence the MLE in this case is

$$(\hat{\beta}, \hat{\mu}) = (+\infty, x^*)$$

An Overlap of the Two Response Types

There is an overlap of the two response types if the smallest dose level with responders is smaller than the largest dose level with nonresponders.

Under the parameterization with μ and β , a degenerate MLE will occur in the extreme case when data suggest that there is no dose–response relation; that is, $\hat{\beta} = 0$. In a three-point design, this means that the proportion of responders is the same for dose x_1 as for dose x_3 . In this case, $\hat{\beta} = 0$ and $\hat{\mu}$ is nonunique or infinite.

Excluding this rare outcome, an overlap implies that the MLE $(\hat{\mu}, \hat{\beta})$ is unique and finite and can be determined from the likelihood equations.

Properties of the Maximum Likelihood Estimator Illustrated

From a practical point of view, after having collected data from all patients in the experiment, we would like to base our inference on standard methods no matter what the underlying risk was for a separation of responders from nonresponders.

If data suggest that there is a separation of responders from nonresponders, there is not much information to gain from the experiment so you would need to supplement your experiment in some way. However, if all parameter estimates exist and are finite, you would like to determine the parameter estimates and make conclusions about the dose–response relation without taking into account the underlying risk of a separation of responders from nonresponders.

Here we demonstrate that the asymptotic inference is valid as soon as $\hat{\beta}$ is finite. We illustrate this in a three-point design with a somewhat larger spacing than in a D-optimal design, design points at quantiles 10%, 50%, and 90%; that is, we chose x_i such that

$$\begin{aligned} P_1 &= 1 - P_3 = 0.10 \\ P_2 &= 1/2 \end{aligned}$$

This naturally represents an idealized situation, because in reality we do not know the position of the center nor the steepness. Placing the middle dose away from the center would increase the risk of a complete or quasi-complete separation, further stressing the importance of a good choice of design points.

The exact distribution for the MLE $(\hat{\mu}, \hat{\beta})$ together with its observed information matrix $J(\hat{\mu}, \hat{\beta})$ was found by

going through the $(n + 1)^3$ possible distinct outcomes in a three-point design for a binary response variable with n observations per dose level.

RESULTS

In a three-point design, $\hat{\beta} = +\infty$ if there are no responders at the lowest dose and no nonresponders at the highest dose. The probability for this event is

$$P(\hat{\beta} = +\infty) \approx (1 - P_1)^n P_3^n \quad (5)$$

The corresponding probability for $\hat{\beta} = -\infty$ is negligible.

In the present investigation, this formula yields the probabilities 0.122, 0.015, and 0.00003 for $n = 10$, $n = 20$, and $n = 50$ observations per dose group, respectively.

In Fig. 1, the exact distribution of $\hat{\beta} - \beta$ standardized by j^{22} is presented for $n = 10$ and $n = 20$.

The j^{22} -standardized distribution curve of $\hat{\beta} - \beta$ follow a standard normal distribution quite well, indicating that the asymptotic inference about β is adequate, as soon as $\hat{\beta}$ is finite. In particular, the median of $\hat{\beta}$ is close to the true β value. Hence if centrality is measured by the median, there is no substantial systematic error in the MLE. Furthermore, as seen in Table 1, the coverage probabilities for one-sided confidence intervals $(-\infty, \hat{\beta} + z_\alpha \sqrt{j^{22}})$ based on a normal approximation are close to the nominal confidence levels for $n = 10$, $n = 20$, and $n = 50$ even when $P(\hat{\beta} = +\infty)$ is substantial. Similar results were found for a D-optimal design and for designs deviating in location and spacing from the D-optimal, except that the probability for a degenerated MLE considerably differed. However, it should be noted that the distribution of $(\hat{\beta} - \beta)/j^{22}$ has no or little probability mass in some intervals but takes large jumps in other points/intervals (Fig. 1). As the location of these intervals is different for different n values, this causes an irregular pattern in the coverage probabilities seen in Table 2.

Fig. 2 shows the $\sqrt{j^{11}}$ -standardized error in $\hat{\mu}$ for $n = 10$, given that $\hat{\beta}$ is finite. The figure illustrates that the $\sqrt{j^{11}}$ -standardized error in $\hat{\mu}$ follows a standard normal distribution fairly well even with only $n = 10$ observations per design point. For the case where $n = 20$ observations per design point, the distribution of the error is even closer to the standard normal distribution. This case has been omitted in Fig. 2 to increase readability. When $\hat{\beta} = +\infty$, use of the observed information from Eq. 3 would indicate a confidence interval for μ of length zero. However, in this case, the likelihood is nonregular, having its maximum on the boundary of the parameter space, so the observed information in Eq. 3 is not justified and should not be used. The results from the exact calculations presented in Table 2 demonstrate that the conditional coverage probabilities are fairly close to the nominal level. It must be stressed that these coverage probabilities are conditional on a finite $\hat{\beta}$, indicating that as soon as we have an

Fig. 1 Empirical distribution of the $\sqrt{j^{22}}$ -standardized error in $\hat{\beta}$ with $n = 10$ (dot-dashed line) and $n = 20$ (short broken) observations per dose level. A $N(0,1)$ is included for reference (solid line)

Fig. 2 Empirical distribution of the $\sqrt{j^{11}}$ -standardized error in $\hat{\mu}$ for the outcomes where $\beta < +\infty$ with $n = 10$ (dot-dashed line). A $N(0,1)$ is included for reference (solid line)

Table 1 Coverage Probabilities for $-\infty, \hat{\beta} + z_{\alpha}\sqrt{j^{22}}$ Intervals

n	97.5% CI	95% CI	90% CI
10	0.9674	0.9592	0.8953

50	0.9698	0.9530	0.8953

overlap of the two response types, asymptotic normality of $\hat{\mu}$ seems to be appropriate. The same results have been qualitatively established not only for a D-optimal design, but also for designs deviating in location and spacing from the D-optimal; for example, a design in Ref. [5] with an extremely large spacing yielding a finite $\hat{\beta}$ with probability of only 0.3. A partial explanation of this remarkable fact is that $\hat{\mu}$ and $\hat{\beta}$ are approximately uncorrelated [note that the expected Fisher information in this case is diagonal (Eq. 4)]

DISCUSSION

The overall conclusion of this work is that three-point designs do not produce systematic errors in the distribution of the maximum likelihood estimator of the steepness parameter, β , but if the design points are too widely spaced, the probability of an infinite $\hat{\beta}$ is unreasonably high. If one succeeds in choosing the spacing according to a D-optimal design, $\hat{\beta}$ seems to be an effective estimator with a reasonably low probability of being infinite, even with only 10 subjects per dose level. However, from a practical point of view, it is difficult to determine the doses D-optimally as it must be based on prior beliefs about the dose-response relationship.

Prior beliefs are required also for a Bayesian analysis of data. Using a data augmentation prior (DAP) (see Ch. 13 in Ref. [4]) would be equivalent to adding some extra observations to the experiment. This would reduce/eliminate

Table 2 Coverage Probabilities for $\hat{\mu} \pm z_{\alpha/2}\sqrt{j^{11}}$ Intervals, Conditional on $\beta < \infty$

n	95% CI	90% CI	80% CI
10	0.9364	0.8782	0.7847
20	0.9474	0.8921	0.7920
50	0.9496	0.8982	0.7972

the risk for infinite or nonunique parameter estimates, but it might then hide the lack of information in the data themselves.

An important practical conclusion of the examples investigated is that once we have an outcome yielding a finite $\hat{\beta}$, asymptotic normality-based confidence intervals are justified for inference about μ given the finite $\hat{\beta}$ and with some extra care also for inference about β .

Therefore the main problem is outcomes with infinite $\hat{\beta}$. Most commonly used statistical computer packages provide warnings that we might have the case of a complete or quasi-complete separation, but some of them nevertheless return finite estimates for all parameters in these situations. It is also important when teaching logistic regression to users of these statistical tools, to discuss the interpretation of a complete or quasi-complete separation of the data.

In practice, what should be done with an experiment that gives an infinite $\hat{\beta}$? First of all, its data indicate that the steepness is greater than expected in advance. The next step would either be to stop the trial here, or more likely, to continue the experiment by including more subjects and more design points in the trial. Different sequential types of procedures have been suggested.^[1]

CONCLUSION

It is concluded that the main problem in three-point designs with a binary outcome is the risk of observing an infinite $\hat{\beta}$.

We need to take this risk into account when designing the experiment. A D-optimal design provides an informative dose–response relation and still has a low risk of observing an infinite $\hat{\beta}$. However, irrespectively of the design, once we have an outcome where all parameter estimates exist and are finite, asymptotic inference is remarkably adequate even in small-sample studies.

McNemar's Test

Robert G. Lehr

Bayer Healthcare Pharmaceuticals, Inc., Montville, New Jersey, U.S.A.

Abstract

McNemar's test is a statistical procedure used to compare two proportions which are dependent or correlated. This entry provides details of the test calculations, variations of the test, sample size calculation methods, discussion of the test characteristics, related confidence intervals, alternative tests, and extensions of the test.

Keywords: Correlated proportions; Discordant pairs; Matched pairs; McNemar's statistic; phi-Correlation; Symmetry.

INTRODUCTION

McNemar's test is a statistical procedure used to compare two proportions which are dependent or correlated. Percentages or proportions of events resulting from 2 observations made on the same or matched experimental units under 2 different conditions may be tested for equality using this procedure. The test may have a one-tailed or two-tailed alternate hypothesis. Details of the test first appeared in a 1947 *Psychometrika* article written by Quinn McNemar (1900–1986), a Stanford University Professor of Psychology and Statistics who made many contributions to psychometric theory. This discourse provides details of the test calculations, variations of the test, sample size calculation methods, discussion of the test characteristics, related confidence intervals, alternative tests, and extensions of the test.

CALCULATION OF THE TEST STATISTIC

The null hypothesis for McNemar's test is the equality of π_1 and π_2 , the two proportions of interest. It may be stated in several equivalent ways, including: $H_0: \pi_1 = \pi_2$, $H_0: \pi_1 - \pi_2 = 0$, and $H_0: OR = 1$, where $OR = (\pi_1/(1 - \pi_1))/(\pi_2/(1 - \pi_2))$. The corresponding alternate hypotheses for a one-tailed test may be $H_0: \pi_1 - \pi_2 > 0$ and $H_0: OR > 1$. A two-tailed alternate hypothesis would be stated using the non-directional “ $\neq$.”

Table 1 below uses a pretreatment-posttreatment scenario to illustrate summarized data for comparing proportions resulting from assessments made on the same or matched experimental units.

In Table 1, $n = a + b + c + d$, b = the number of subjects classified a success post but not pre, c = the number of subjects classified a success pre but not post,

$n_1 = a + b$ = the number of observed pretreatment successes, $n_s = a + c$ = the number of observed posttreatment successes, $p_1 = n_1/n = (a+b)/n$ = the observed posttreatment proportion of success, and $p_2 = n_2/n = (a + c)/n$ = the observed pretreatment proportion of success. The frequencies b and c are usually referred to as mismatch-cell or discordant-pair frequencies, as the pair of observations represents different responses.

A statistic which may be used to quantify the treatment effect and estimate the population difference is $(p_1 - p_2) = (b - c)/n$, the difference in proportions of success which is an estimate of $\pi_1 - \pi_2$. When p_1 and p_2 are likely to be near 0 or 1 and their difference is likely to be small, the odds ratio, $(p_1/(1 - p_1))/(p_2/(1 - p_2)) = ad/bc$, may be preferred to compare the two.

The test statistic most commonly used for McNemar's test is

$$T_u = \frac{(b - c)^2}{(b + c)} \quad (1)$$

using the notation of Table 1. It is approximately distributed as chi-square with one degree of freedom.

The test statistic in Eq. 1 can be derived in several ways, two of which were provided in the original entry.^[1] As $(p_1 - p_2) = (b - c)/n$ is not dependent on a or d , the numbers of concordant pairs, a statistic may be formed using only the expected cell frequencies for the discordant cells under the null hypothesis. Substituting these two expected values, $(b + c)/2$, into the usual chi-square (observed – expected)²/(expected) expression yields Eq. 1 directly with some algebraic simplification. Alternately, creating a Wald statistic by forming a ratio of the difference of the two correlated proportions divided by the standard deviation of the difference results in an equivalent test using a statistic which is approximately distributed as Normal (0,1).

Table 1 Response Frequencies

		Pretreatment		
		Success	Failure	
Posttreatment	Success	<i>a</i>	<i>b</i>	<i>n</i> ₁
	Failure	<i>c</i>	<i>d</i>	
		<i>n</i> ₂		<i>n</i>

The continuity-corrected McNemar chi-square test uses the statistic

$$T_c = \begin{cases} (b - c - 1)^2 / (b + c) & \text{if } b > c, \\ (b - c + 1)^2 / (b + c) & \text{if } b < c, \\ \text{and } 0, & \text{if } b = c \end{cases} \quad (2)$$

This given variation^[2] is analogous to the Yates correction for comparing independent proportions.

An exact version (T_c) of McNemar's test, described by Mosteller,^[3] may be performed as follows: If $c > b$, the p -value = the probability of getting (c or more) or (b or less) successes in a binomial experiment of $b + c$ trials each with probability of success $p = 1/2$, that is $B(\geq c, b + c; 1/2) + B(\leq b, b + c; 1/2)$, where

$$B(\leq x, n; p) = \sum_x^n \frac{n!}{x!(n-x)!} p^x (1-p)^{n-x}$$

Although McNemar only gives the first of these three versions of his test in the seminal 1947 paper, he mentions the latter two in his textbook *Psychological Statistics*.^[4] It is likely that several statisticians independently derived comparable test statistics at approximately the same time, but McNemar's version was apparently the first to reach print. Siegel's work may be the first textbook^[5] in which the method was called "McNemar's test."

An interesting relationship between McNemar's test and the Cochran Mantel-Haenszel (CMH) test is described by Agresti^[6] in his *Categorical Data Analysis* book. Each pair of binary responses may be represented as a 2×2 table, and then the CMH test for conditional independence for the set of 2×2 tables is a test for marginal homogeneity in the collapsed table.

AN EXAMPLE

A researcher instructs 50 patients with a mild rash on both arms to apply a steroid cream to one arm for 14 days, and a pink drying lotion to the other arm. The condition of interest is complete healing of all lesions. Table 2 gives the results.

The steroid cream had a better healing rate with 66% of the arms healed compared to 46% for the pink drying lotion. Using Eq. 1, the McNemar test statistic is

Table 2 Fourteen-day Complete Healing Rates

		Pink drying lotion	
		Healed	Not healed
Steroid cream	Healed	8	25
	Not healed	15	2

$X^2 = (25 - 15)^2 / (25 + 15) = 2.5$. The corresponding two-tailed probability from a chi-square distribution with one degree of freedom is $p = 0.113$. Using the 0.05 significance level, the data do not provide sufficient evidence to conclude that the two treatments differ in healing effect.

APPLICATIONS OF McNEMAR'S TEST

As is evidenced by the earliest references, McNemar's test has seen extensive use in the behavioral sciences. It is the simplest test to use for comparing binary data for short- or long-term studies involving matched subjects. Changes for identical twins in a given characteristic, increase or decrease in a given score for the same test subject, or success or failure on a given test for a matched pair of subjects are all reasonable applications of this test.

Any study using a design that involves two observations on a binary variable on the same subject may be analyzed with McNemar's test. Preintervention and postintervention results, two different interventions on different locations, or two observations taken at successive time points are all examples of where the test may be used. Diagnostic imaging studies often are designed to obtain two scans on the same area of the same subject and compare the diagnostic accuracies of readers using the scans to determine presence or absence of a given condition.

Studies in which a binary or dichotomous variable is evaluated on matched pairs of patients may also be analyzed using McNemar's test. Long-term epidemiology studies on twins, other siblings or family relations, or subjects matched on a set of demographic and background factors are among the most popular designs.

ALTERNATIVE TESTS

Several tests have been proposed as alternatives to McNemar's test for the equality of two correlated proportions. None exhibit the simplicity or frequency of use.

Bennett and Underwood^[7] discuss a statistic formed by adding 1/2 to each cell frequency, which leads to the statistic $T_{u*} = (b - c)^2 / (b + c + 1)$. They observe that this statistic seems to perform better than the previously mentioned corrected McNemar statistic based on empirical investigations.

A Wald statistic that results from the application of a general method proposed by Grizzle, Starmer, and Koch^[8]

uses a variance estimator not restricted by the null hypothesis. The statistic was put forth as an alternative to the more general Q statistic of Cochran,^[9] which is in a sense a more general version of McNemar's test. No claims are made regarding the performance of the statistic relative to that of the prior tests.

Suissa and Shuster^[10] proposed a method of calculating the exact significance level for the statistic formed by the square root of the McNemar statistic. The procedure uses the complete domain of the nuisance parameter representing the probability of a discordant pair under the null hypothesis.

May and Johnson^[11] compare the size and power of the uncorrected, corrected, and exact versions of McNemar's test already mentioned and several other tests. They found that the Wald statistic tends to be anticonservative while the continuity-corrected version of McNemar's test tends to be overly conservative.

Irony, Pereira, and Tiwari^[12] suggest a Bayesian hypothesis test for the comparison of two correlated proportions. The test consists of evaluating the posterior odds ratio, the ratio of the posterior probabilities, that is, the population proportion of one of the discordant-pair cells to the total of the two discordant-pair cells.

Lloyd^[13] has proposed an exact unconditional test of unequal effects from binary matched pairs. Starting with an estimate of the nuisance parameter from an inexact test, he eliminates the residual dependence by maximization. He calls the resulting probabilities E + M *p*-values, presumably for "estimate and maximize."

SAMPLE SIZE DETERMINATION

Different approaches to calculating sample size requirements for the McNemar test have been given by several authors. The methods vary with respect to approach (conditional or unconditional), parameters that need to be specified, and whether they are asymptotic or exact.

One of the first methods proposed for estimating sample size for McNemar's test was proposed by Miettinen.^[14] Miettinen's equation for a one-sided test states that the required sample size is

$$n = \left[z_{\alpha} \Psi + z_{\beta} (\Psi^2 - 1/4 \delta^2) + \Psi^{1/2} \right]^2 / \Psi \delta^2 \quad (3)$$

where δ is the detectable difference, Ψ is the proportion of mismatches, and z_{α} and z_{β} are the usual normal values.

Schlesselman^[15] gives a two-step method requiring specification of the estimated proportion of discordant pairs and odds ratio to be detected. The required number of experimental units resulting in discordant pairs is then determined, leading then to an estimate of the total units required.

Connor^[16] used an unconditional multinomial-based approach and derived an equation similar to that of

Miettinen's. He suggested the use of an independence assumption if no information regarding discordant-pair frequency was available.

Dupont^[17] developed a method of estimating the sample size for McNemar's test which required the specification of the probability of exposure for control patients, an odds ratio to be detected, and a correlation coefficient for exposure in matched pairs of case-control studies.

Connett, Smith, and McHugh^[18] derive a formula for McNemar's tests with a completely unconditional approach. They state that the derivation is analogous to that used by Fleiss^[19] for the unmatched design. They provide a proof that their unconditional method will always produce a result equal to or greater than Schlesselman's conditional formula.

Using Connett's equation, Machin et al.^[20] have constructed tables of sample sizes for McNemar's test. Various values for the alternate hypothesis odds ratio and the proportion of discordant pairs cover 17 pages.

Parker and Bregman^[21] developed a sample size formula that allows adjustment for varying probability of discordant pairs among matched pairs. They demonstrate that allowing for this heterogeneity increases the calculated sample size requirements.

Lachenbruch^[22] proposed a method that provided a range of possible sample sizes based on the smallest and largest possible numbers of discordant pairs. The method is proposed for situations where estimates of discordant-pair frequencies are not readily available.

Several authors have evaluated and/or compared one or more sample size method for McNemar's test. Duffy^[23] compared Miettinen's asymptotic formula against exact powers, and concluded the asymptotic formula was generally adequate. Lachin^[24] thoroughly analyzed the methods previously mentioned among others and discussed which tend to be conservative and anticonservative. He demonstrated that the differences among the methods can be traced to the variance estimates under the alternate hypotheses. Royston^[25] compared several conditional and unconditional approaches and suggested a strategy for sample size choice based on a binomial unconditional estimate.

A quick formula that provides an easy method for obtaining rough sample size estimates for McNemar's test requires the specification of a pair of proportions and estimate of the correlation between them.^[26] For a two-tailed McNemar test with alpha level 0.05, the following relation specifies a sample size, which provides an approximate power of 0.80 to detect a difference d between proportions p_1 and p_2

$$n = \frac{16pq(1-r)}{d^2} \quad (4)$$

where n is the size of the sample, $p = (p_1 + p_2)/2$, $q = 1 - p$, $d = |p_2 - p_1|$, and r is the phi correlation coefficient. The possible values for r are dependent on p_1 and p_2 , and do not in general span the entire range of -1 to 1 .

Other authors have developed sample size estimation methods for extensions of McNemar's test. Woolson, Bean, and Rojas^[27] proposed a method for Cochran's test. Feuer and Kessler^[28] derive a test statistic and sample size method for testing whether the marginal changes in two independently sampled tables are equal. Lu and Bean^[29] discuss the problem of estimating sample size for one-sided equivalence based on McNemar's test.

DISCUSSION OF THE CHARACTERISTICS OF McNemar's TEST

Some users are uncomfortable with McNemar's test because the numbers the statistic used do not reflect the entire sample size; so at first glance the test does not seem to be a comparison of the two paired proportions.^[30] These features are, however, just a consequence of the pairing. Although only the frequencies or proportions from the mismatch cells are used in the calculation, all cases contribute to the inference about whether the marginal proportions differ.^[6]

The relationship involving the paired values can be expressed in several ways, two of which have been mentioned previously. The quantities Ψ and r affect power, required sample size, and operating characteristics of McNemar's test. The symbol Ψ , used here to represent the proportion of discordant pairs, unfortunately, is also used to denote odds ratios. The correlation coefficient r is the familiar Pearson r calculated on zeros and ones, and has a simpler form expressed in terms of the four cell frequencies from the 2×2 table, for which case it is more commonly denoted ϕ (phi). In terms of the quantities in Table 1, this simpler form is

$$r = \phi = \frac{(ad - bc)}{\sqrt{(a+B)(c+d)(a+c)(b+d)}} \quad (5)$$

The two quantities r and Ψ , which both characterize the degree of relationship between the paired variables, are related. For a fixed pair of proportions, the correlation r and the proportion of discordant pairs Ψ are functions of one another, i.e., r , generally, decreases as Ψ increases. The relationship between Ψ and r for a given p_1 and p_2 can be specified by^[26]

$$\Psi = p_1 + p_2 - 2p_1p_2 - 2r \times \sqrt{p_1(1-p_1)p_2(1-p_2)} \quad (6)$$

The range of possible values which Ψ may take is from $|p_2 - p_1|$ to $p_1 + p_2$ or $2 - (p_1 + p_2)$, whichever is smaller. A practical lower bound of $p_1(1 - p_2) + p_2(1 - p_1)$, the proportion of discordant cells which would result from independence, is also useful for some situations. As previously stated, r is a function of Ψ , p_1 , and p_2 , and may thus be obtained using

$$r = \frac{(p_1 + p_2 - \Psi - 2p_1p_2)}{2\sqrt{p_1(1-p_1)p_2(1-p_2)}} \quad (7)$$

a direct inversion of Eq. 6. Substituting the value of Ψ corresponding to independence will produce an r value of 0. Substituting the minimum Ψ of $p_2 - p_1$ into Eq. 7 produces

$$r = \sqrt{\frac{p_1(1-p_2)}{p_2(1-p_1)}} \quad (8)$$

The right-hand side of Eq. 8 is the square root of the odds ratio where $p_1 < p_2$. This gives an easy way of remembering the maximum possible r given proportions p_1 and p_2 . Although r may be less than 0, for most practical situations values ranging from 0 to the square root of the odds ratio may be assumed.^[26]

If only a difference δ is specified without p_1 and p_2 , the value of r has a maximum of

$$r_{\max} = \frac{(1 - \delta)}{(1 + \delta)} \quad (9)$$

which is reached when $(p_1 + p_2)/2 = 0.5$, i.e., $p_1 + p_2 = 1$.

RELATED CONFIDENCE INTERVALS

Asymptotic confidence intervals (CIs) for the difference of correlated proportions ($\pi_1 - \pi_2$) are referenced in some statistics textbooks discussing categorical data analysis. Using the notation of Table 1 and the ensuing discussion, a formula for an asymptotic CI given by Fleiss^[19] is $((p_2 - p_1) + (1.96\text{se}_{p_2-p_1}) + 1/n)$, where

$$\text{se}_{p_2-p_1} = \sqrt{(a+d)(b+c) + 4bc/n} \sqrt{n}$$

Breslow and Day^[31] suggested a CI that can be obtained by generating an exact CI for the proportion $b/(b+c)$ from Table 1 and then translating these limits back into odds ratios.

Armitage and Berry^[32] suggested a CI which can be obtained in a similar way to that used by Breslow and Day for the differences $(p_2 - p_1)$ which would result given the b and c cells. This interval, in terms of the original cell frequencies, is

$$\left(\frac{b+c}{n} \right) \left(\frac{2b}{b+(c+1)F_{[2(c+1), 2b]}} - 1 \right), \dots, \left(\frac{b+c}{n} \right) \left(\frac{(2b+2)F_{[2(b+2), 2c]}}{c+(b+1)F_{[2(b+2), 2c]}} - 1 \right)$$

Exhaustive empirical investigations suggest that this interval is perfectly consistent with the exact version of the McNemar test in the sense that the test rejects H_0 if and

only if the CI excludes 0.^[33] Lloyd^[34] points out a coverage problem with these two intervals under certain conditions, and suggests an ad hoc adjustment for these situations.

Several other authors have proposed different CI methods for differences in correlated proportions. Tango^[35] proposed a score-based interval for the difference of two matched proportions, which he found to have better coverage than several other intervals used for comparison. Agresti and Min^[36] propose a simple adjustment for the usual Wald CI for the difference of two proportions, which consists of adding 2 to each observed frequency. They find that this adjustment results in an interval that provides coverage much closer to the nominal value. May and Johnson^[37] compare several CIs for correlated binary proportions. Newcombe^[38] also compared several different CI methods and proposed another.

GENERALIZATIONS AND EXTENSIONS OF McNEMAR'S TEST

Statistical methods that generalize McNemar's test to closely related problems have been developed by several statisticians. McNemar's test compares two proportions resulting from the same or matched units, whereas Cochran's Q test^[9] compares n such proportions. The statistic is distributed approximately as chi-square with $n - 1$ degrees of freedom. Cochran's Q statistic is identical to the McNemar statistic when $n = 2$.

The McNemar test is sometimes referred to as a test of symmetry across a diagonal in a 2×2 table. Bowker's test is used to assess symmetry across a diagonal in a square table of higher dimension.^[39]

Another generalization of the McNemar test applies to paired ordinal categorical data, a natural extension of the binary case to three or more categories. Agresti^[40] describes a test that is an adaptation of the Mann-Whitney test, which takes into account the ordering of the variables.

Hamdan, Pirie, and Arnold^[41] proposed methods for testing the simultaneous equality of proportions of unlike pairs in several independent populations.

Paired-binary methods that extend McNemar's test to clustered data have been developed by Eliasziw and Donner,^[42] Obuchowski,^[43] and Durkowski et al.^[44] These methods may be applied when the clustering involves sampled individuals in different geographical regions. Another application is the consideration of multiple measured sites or units on the same individual to comprise a cluster.

Other specialized situations leading to extensions of McNemar's test have drawn the attention of several authors. Marascuillo and Serlin^[45] proposed a test to compare paired results for two or more independent treatments for identical change. Prescott's test and the Mainland-Gart test allow for a period effect in comparing paired proportions resulting from a crossover trial.^[46] Lachenbruch and

Lynch^[47] propose several modifications of McNemar's procedure to assess equivalence using a compound null hypothesis. Klingenberg and Agresti^[48] have proposed a multivariate extension of McNemar's test and show that it is a generalized score test under a GEE approach.

CONCLUSIONS

McNemar's test is a simple and widely used procedure for comparing two dependant or matched proportions. Although it was developed in 1947, no alternative has replaced it as the most commonly used method for its purpose. Since its introduction, statisticians have been proposing alternatives, improvements, sample size methods, CIs, and extensions related to the test.

MCP-Mod: Dose–Response Testing and Estimation

Björn Bornkamp

Abstract

Multiple comparison procedures and modeling (MCP-Mod) is a method for dose–response testing and dose–response estimation under model uncertainty. The dose–response modeling is based on a set of candidate dose–response shapes that is predefined at the design stage of the trial. The methodology consists of two main steps. The first step is a statistical test for a dose–response signal, assessing whether there is any effect of the test doses over placebo (the MCP step). This is performed by utilizing a multiple contrast test procedure, where each of the candidate shape is represented by a contrast. In the second step, the dose–response curve is estimated based on model selection or model averaging techniques, utilizing the predefined candidate dose–response models.

Keywords: Dose finding; Dose–response; Model uncertainty; Multiple contrast test; Phase II study.

INTRODUCTION

Multiple comparison procedures and modeling (MCP-Mod) is a method for dose–response testing and dose–response estimation under model uncertainty. The dose–response modeling is based on a set of candidate dose–response shapes that is predefined at the design stage of the trial. The methodology consists of two main steps. The first step is a statistical test for a dose–response signal, assessing whether there is any effect of the test doses over placebo (the MCP step). This is performed by utilizing a multiple contrast test procedure, where each of the candidate shapes is represented by a contrast. In the second step, the dose–response curve is estimated based on model selection or model averaging techniques, utilizing the predefined candidate dose–response models.

The goal of this entry is to provide an introduction and review of the MCP-Mod methodology. The section “Dose finding and MCP-Mod” contains a high-level introduction to the procedure, and then section “MCP-Mod: Literature Review and Historical Overview” reviews the historical development of MCP-Mod and references related to MCP-Mod. The sections “MCP-Mod for Normally Distributed Data” and “MCP-Mod for General Data” provide a more detailed technical overview of the method, first for normally distributed data and then for general parametric models. The section “Design Aspects” considers study design aspects related to MCP-Mod. The section “Scope of MCP-Mod” presents more details on which

dose-finding problems MCP-Mod applies to and to which it does not apply, and what alternative methods can be useful in other situations. The final section reviews software implementations available for MCP-Mod.

DOSE-FINDING AND MCP-Mod

A general overview of dose-finding in the whole clinical drug development is given in the book by Ting.^[1] The MCP-Mod methodology applies primarily to phase II dose-finding studies. These studies play an important role in drug development—they are the last study/studies done before the start of the confirmatory studies in phase III. Because of this, they play an important role both in supporting the go/no-go decision to phase III and also in terms of dose-finding and dose- selection for phase III clinical trials.

The primary regulatory guidance for dose finding is the ICH E4 document on Dose–Response Information to Support Drug Registration. Despite the fact that this document is now years old, dose-finding and dose selection are often inadequately performed. For example, Cross et al.^[2] examined post approval changes in dosages during the time period 1980–1999. They concluded that around 20% of the drugs had their dosages changed. In 80% of those cases, the dose was reduced. Sacks et al.^[3] provided an overview on the scientific reasons for delay or denial of approval of a drug by the Food and Drug Administration (FDA) during the time period of 2000–2012. Of those submissions that

were not approved the first-time, uncertainties related to dose selection was one of the most common deficiencies.

A more prominent role of dose–response modeling in phase II studies was identified as a way of improving the design and analysis of dose-finding in drug development. Traditionally, phase II dose–response studies are designed for pair-wise testing approaches. These methods do not directly focus on selection of a specific dose or appropriate determination of the full dose–response curve. In addition, if multiple test strategies are used, there is a further penalty for utilizing multiple dose levels. When analyzing a study for dose–response (trend) testing and estimation, more emphasis will be put on estimation of the dose–response curve and so more informative designs should result, in the sense of being able to investigate more doses and more informatively selected doses.

An extensive overview and simulation-based comparison of different methods is provided in the white papers of the Pharmaceutical Research and Manufacturers of America (PhRMA) group on adaptive-dose ranging studies^[4,5] studying parametric and non-parametric as well as Bayesian and non-Bayesian methods. Parametric methods to estimate the dose–response curve using the sigmoid Emax dose–response model have been proposed, for example, in the article by Thomas^[6] in a Bayesian setting and in the article by Dragalin, Hsuan, and Padmanabhan^[7] in a non-Bayesian setting. Empirical evidence of the appropriateness of the sigmoid Emax model using a large-scale meta-analysis is provided in the article by Thomas, Sweeney, and Somayaji.^[8] Non-parametric Bayesian methods for estimating the dose–response curve based on dynamic linear models have been considered,

for example, in the articles by Grieve and Krams^[9] and Berry et al.,^[10] often coupled with the use of adaptive designs. Non-Bayesian flexible methods to estimate the dose–response curve based on splines are, for example, discussed in the articles by Desquilbet and Mariotti^[11] and Helms et al.^[12] The MCP-Mod method discussed in detail here is an approach somewhere between the parametric and non-parametric modeling, because a candidate set of parametric dose–response curves is used to model the dose–response curve. Depending on the diversity of the candidate models, this approach is rather flexible in terms of estimating the dose–response curves.

Fig. 1 outlines the steps it takes to implement the MCP-Mod procedure in a dose-finding trial. At the trial design stage, one needs to include design considerations as in any other clinical trial, for example, selection of study population and study end point. What is special about MCP-Mod is that a preselection of candidate dose–response models is performed, which will be utilized as part of the methodology. Ideally, this candidate set of dose–response shapes should reflect the available clinical information on the shape of the dose–response curve. That is when the uncertainty on the shape is large, a broad set of candidate shapes and models are selected, and when the uncertainty is less, a more narrow set is selected. Together with an assumption on the maximum effect size of the drug, the chosen candidate set of models can not only be used to derive the total sample size of the trial, but also to evaluate the necessary doses needed for efficient estimation of the dose–response curve or target doses of interest. Section “Design Aspects” will elaborate more on the selection of the candidate set and design considerations.

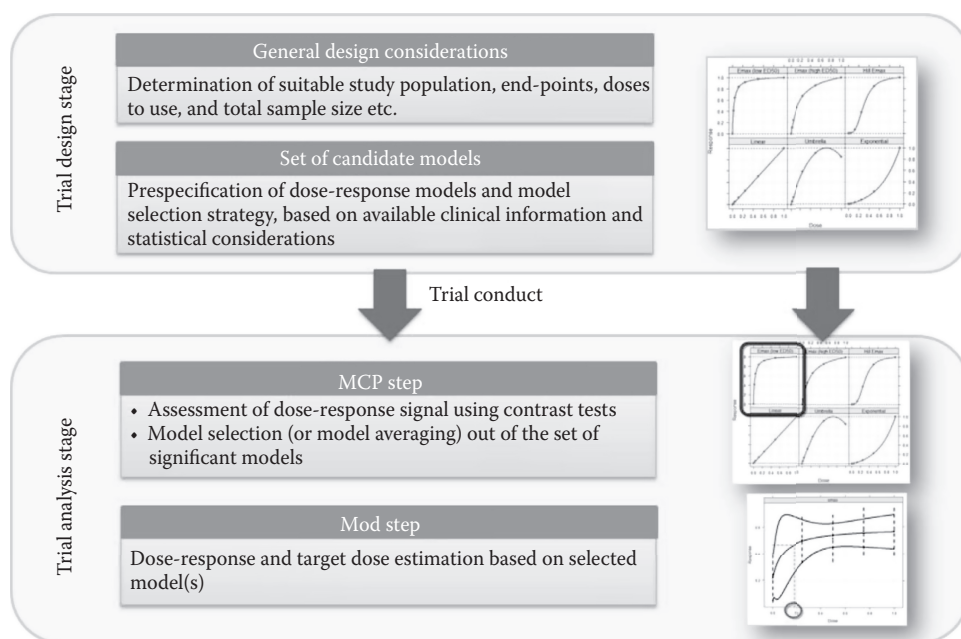

Fig. 1 Overview of the different steps involved, when implementing the MCP-Mod procedure in a dose-finding trial

At the analysis stage, the MCP-Mod method consists of two main steps. The first step is a statistical test for a dose–response signal, assessing whether there is any effect of the test doses over placebo (the MCP step). This is performed by utilizing a multiple contrast test that is optimized for the candidate shapes included. In the second step, the dose–response curve is estimated based on model selection or model averaging techniques, utilizing the predefined candidate dose–response models. The analysis methodology will be discussed in more detail in the sections “MCP-Mod for Normally Distributed Data” and “MCP-Mod for General Data.”

MCP-Mod: LITERATURE REVIEW AND HISTORICAL OVERVIEW

The original MCP-Mod procedure of Bretz, Pinheiro, and Branson^[13] was motivated by the work of Tukey, Ciminera, and Heyse,^[14] who proposed to use several trend tests simultaneously based on different functional dose–response descriptions and to subsequently adjust the resulting *p* values for multiplicity. Since then, the methodology has been subject to several investigations. Pinheiro, Bornkamp, and Bretz^[15] discussed practical considerations regarding the implementation of this methodology, including sample size calculations for the MCP part. Dette et al.^[16] constructed optimal designs for target dose estimation to determine the optimum location of doses and allocation of patients to the dose levels, taking model uncertainty into account. Klingenberg^[17] applied the MCP-Mod approach to proof-of-concept studies with binary responses. Tao et al.^[18] incorporated both efficacy and safety end points through joint modeling. Dette et al.,^[19] Baayen, Hougaard, and Phipper,^[20] and Gutjahr and Bornkamp^[21] investigated the use of likelihood ratio tests instead of multiple contrast tests. Miller^[22] and Franchetti, Anderson, and Sampson^[23] extended the MCP-Mod approach to flexible two-stage designs that include the possibility to perform adaptations (e.g., adding or dropping doses) under a strict family-wise error rate (FWER) control. Bornkamp et al.,^[24] Vandemeulebroecke et al.,^[25] and Mercier et al.^[26] investigated the MCP-Mod procedure in response-adaptive designs, addressing two major challenges in dose-finding studies—uncertainty about the dose–response models and large variability in parameter estimates. Schorning et al.^[27] investigated the Mod step of MCP-Mod in more detail and compared different model selection criteria and model selection versus model averaging, using a simulation study. While no uniformly best model selection criteria can be established, model averaging approaches outperform the model selection approaches in the simulation scenarios covered. König et al.^[28] extended the MCP part of the MCP-Mod procedure using the closed test principle so that pair-wise comparisons between test treatment and control can be performed, controlling the FWER for

these comparisons, so that the MCP part of MCP-Mod could also be utilized in confirmatory studies. A general overview of MCP-Mod and many practical implementation aspects were provided by Xun and Bretz.^[29] Design aspects such as ways of determining the doses to utilize in a dose-finding trial and the total sample size are reviewed in the article by Pinheiro and Bornkamp.^[30]

In 2014, the MCP-Mod procedure received a qualification opinion by the European Medicines Agency, [Committee for Medicinal Products for Human Use (CHMP)] as an efficient statistical methodology for model-based design and analysis of phase II dose-finding studies under model uncertainty.^[31] In 2016, the methodology received a fit-for-purpose determination by the FDA.^[32]

MCP-Mod FOR NORMALLY DISTRIBUTED DATA

Assume a primary response variable *y* for a given set of parallel groups of patients corresponding to test doses *d*₂, *d*₃, ..., *d*_{*k*} plus placebo *d*₁, for a total of *k* arms. For the purpose of dose–response signal testing and estimating target doses, we consider the model specification:

$$y_{ij} = \mu_i + \varepsilon_{ij}, \varepsilon_{ij} \sim N(0, \sigma^2), j = 1, \dots, n_i, i = 1, \dots, k \quad (1)$$

where the mean response at dose *d*_{*i*} can be represented as $\mu_i = \mu(d_i, \theta)$ for some dose–response model $\mu(\cdot)$, parameterized by a vector of parameters θ , *n*_{*i*} denotes the number of patients allocated to dose *d*_{*i*}, and ε_{ij} is the error term for patient *j* within dose group *i* (assuming independent residuals). We note that most dose–response models used in practice can be written as $\mu(d, \theta) = \theta_0 + \theta_1 f^0(d, \theta_2)$, and $f^0(d, \theta_2)$ is typically a non-linear transformation of the dose levels depending on θ_2 . The parameters θ_0 and θ_1 determine location and scaling of the function *f*. An example for f^0 is $f^0(d, \theta_2) = d/(d + \theta_2)$, resulting in the (hyperbolic) Emax model and where θ_2 is the ED₅₀ parameter of the Emax model. More dose–response models are given in

Table 1 Example dose–response models often used in clinical trials^a

Model name	$f(d, \theta)$	(*)
Linear	$E_0 + \delta d$	
Emax	$E_0 + E_{\max} d / (ED_{50} + d)$	ED ₅₀
exponential	$E_0 + E_1 (\exp(d/\delta) - 1)$	δ
Sigmoid	$E_0 + E_{\max} d^h / (ED_{50}^h + d^h)$	$(ED_{50}, h)'$
Emax		
Beta model	$E_0 + E_{\max} B(\delta_1, \delta_2) (d/D)^{\delta_1} (1 - d/D)^{\delta_2}$	$(\delta_1, \delta_2)'$

^aColumn (*) lists for each model the parameters that determine the shape of the model. For the beta model, $B(\delta_1, \delta_2) = (\delta_1 + \delta_2)^{\delta_1 + \delta_2} / (\delta_1^{\delta_1} \delta_2^{\delta_2})$ and for the quadratic model $\delta = \frac{\beta_2}{|\beta_1|}$.

Table 1, with example shapes for each model presented in Fig. 2. More details on these dose–response models can be found in the article by Pinheiro, Bretz, and Branson^[33] and a guide on how to select candidate dose–response models for a specific trial is given in the section “Design Aspects.”

The first step of MCP-Mod is to identify a set of M parameterized candidate models together with parameter values for their standardized versions. When used with the doses planned for the trial, $d_1, \dots, d_k$, these candidate models produce mean response vectors $\boldsymbol{\mu}_m = (\mu_{m1}, \dots, \mu_{mk})$, where $\mu_{mi} = \mu_m(d_i, \theta_{2m})$ with a specified parameter θ_{2m} and μ_m is the m^{th} dose–response function, $m = 1, \dots, M$.

The second step is to test each of the dose–response shapes in the candidate set using a single contrast test, with coefficients chosen to maximize the power of the test when the true underlying mean response equals $\boldsymbol{\mu}_m$. This approach formulates the test for a dose–response trend in terms of a linear contrast hypothesis $\mathbf{c}'\boldsymbol{\mu}$, where $\mathbf{c}$ is a contrast vector subject to $\sum_i c_i = 0$ and $\boldsymbol{\mu}$ is the true mean at the dose levels. For a given vector $\boldsymbol{\mu}$, optimum contrast coefficients for model testing are proportional to $n_i(\mu_i - \mu^*)$, $i = 1, \dots, k$, where $\mu^* = \boldsymbol{\mu}'\mathbf{1}/k$. After

normalization, this leads to the unique solution (up to the sign) $\mathbf{c}/\|\mathbf{c}\|$. Each of M possible dose–response shape gets represented by one contrast $\mathbf{c}_m = (c_{m1}, \dots, c_{mk})$. For example, a linear contrast test for equally spaced doses and balanced patient allocation is defined such that the difference of any two adjacent contrast coefficients is a constant. Assuming that the linear model has been included in the candidate model set, the linear contrast test is then a powerful test to detect the linear trend. Similarly, any dose–response relationship characterized through $\boldsymbol{\mu}_m$ can be tested equally powerfully by selecting an appropriate contrast test, whose coefficients are defined in dependence of the assumed $\boldsymbol{\mu}_m$. Note that contrast tests are shift and scale invariant, and thus it is sufficient to work with the standardized modeling functions f^0 .

The third step is to test for an overall dose–response signal. The single contrast test is defined as:

$$T_m = \frac{\sum_{i=1}^k c_{mi} \bar{Y}_i}{S \sqrt{\sum_{i=1}^k c_{mi}^2 / n_i}}, \quad m = 1, \dots, M, \quad (2)$$

Fig. 2 Example dose–response shapes for the models in Table 1. For simplicity the dose range is from $[0,1]$, the placebo effect is assumed to be 0, and the maximum effect is assumed to be 1

Where,

$$S^2 = \sum_{i=1}^k \sum_{j=1}^{n_i} (Y_{ij} - \bar{Y}_i)^2 / (N - k) \quad (3)$$

denotes the variance estimate and $N = \sum_i n_i$, the total sample size. Under the null hypothesis $H: \mathbf{c}'\boldsymbol{\mu} = 0$ of no dose-response effect, i.e., $\mu_1 = \dots = \mu_k$, and under the distributional assumptions from above, $T_1, \dots, T_M$ jointly follow a central multivariate t distribution with $N - k$ degrees of freedom and the correlation matrix only depends on the sample sizes and the correlations between the different contrasts. Note that for the data analysis step, the critical value, contrast weights, etc. might need to be recalculated at the analysis stage due to dropouts, covariate effects, etc.

The final test statistic $T_{\max}$ is based on the maximum contrast test, i.e., $T_{\max} = \max_m T_m$. A dose-response signal is verified when this maximum statistic $T_{\max}$, and thus at least one single contrast test is statistically significant while controlling the FWER at prespecified level α . Let $q_{1-\alpha}$ denotes the multiplicity adjusted critical value. A dose-response signal is then established if $T_{\max} \geq q_{1-\alpha}$. In fact, any dose-response model with a test statistic larger than $q_{1-\alpha}$ can be declared statistically significant at level α . If no candidate model is statistically significant, the MCP-Mod procedure stops indicating that a dose-response signal cannot be established from the observed data.

The fourth step is to select one model out of the reference set or to perform model averaging. Model selection criteria such as the Akaike information criterion (AIC) or Bayesian information criterion (BIC) can be used for model selection or model averaging. An overview of different approaches is presented in the study by Schorning et al.^[27]

The fifth and final step consists of estimating the dose-response curve and target doses of interest using the dose-response model(s) selected in the previous step.

MCP-Mod FOR GENERAL DATA

In this section, we describe an extension of the MCP-Mod procedure to general parametric end points and more complex situations than discussed previously. For example, the response variable might be a count, binary or time-to-event variable, or in a normally distributed setting, the variance might be different at different dose groups (e.g., proportional to the dose or the mean response). In addition, the final analysis has to be usually adjusted for relevant covariates (e.g., region, age, etc.). Patient measurements are often recorded over time (necessitating the use of longitudinal models), and patients might receive more than one treatment (such as in crossover or incomplete block designs). The core ideas of MCP-Mod remain applicable in

these situations, as sketched in the following and laid out in the article by Pinheiro et al.^[34] in more detail.

Let $\mathbf{y}$ denote the response vector of an experimental unit in the trial (e.g., a patient) which has been assigned a dose d (the formulation can easily be extended to the case of multiple doses). We assume that the residual distribution function is given by $\mathbf{y} \sim F(\mathbf{z}, \boldsymbol{\eta}, \boldsymbol{\mu}(x))$, where $\boldsymbol{\mu}(d)$ denotes the dose-response parameter, $\boldsymbol{\eta}$ the nuisance parameters (fixed effects and random effects), and $\mathbf{z}$ the possible covariates. The key features of MCP-Mod can then be formulated with respect to $\boldsymbol{\mu}(d)$, including:

- accounting for uncertainty in the dose-response model via a set of candidate dose-response models
- testing for a dose-response signal via optimal contrasts based on plausible dose-response shapes
- model selection or model averaging to combine different models
- dose-response estimation and dose selection using non-linear regression.

Because all dose-response information is assumed to be represented by $\boldsymbol{\mu}(d)$, the interpretability of this parameter is critical for communicating with clinical teams, choosing candidate dose-response shapes, specifying clinically relevant effects, and etc.. As an example, consider the Weibull distribution, which is typically parameterized by a scale parameter λ and shape parameter α , neither of which is easily interpretable. For the purpose of interpretability, the model could be reparameterized in terms of the median time-to-event $\mu = \log(2)^{1/\alpha} / \lambda$, and α , and then use μ as an interpretable dose-response parameter.

Let $\hat{\boldsymbol{\mu}}$ denotes the vector of estimated dose-response parameters under an analysis of variance (ANOVA) parameterization, obtained using the appropriate estimation method for the general parametric model above via maximum likelihood (ML), generalized estimating equations, partial likelihood, etc. The key assumption needed for this general version of MCP-Mod to work is that the response estimates $\hat{\boldsymbol{\mu}}$ at the doses are asymptotically multivariate normal distribution with covariance matrix $\mathbf{S}$. This approximation can be shown to hold for most parametric estimation problems, such as, generalized linear models, parametric time-to-event models, mixed-effects models, etc. The MCP step consists of specifying a set of candidate models for the dose-response relationship $\boldsymbol{\mu}(d)$. Similar to the original MCP-Mod approach, each of the candidate model shape determines an optimal contrast for a trend test to evaluate the associated dose-response model signal. The optimal contrasts are applied to the previously described ANOVA-type estimates $\hat{\boldsymbol{\mu}}$, with the associated asymptotic distribution used for implementing the corresponding tests (i.e., critical values and p values). It can be shown that the (optimal) contrast for testing the hypothesis that $\mathbf{c}'\boldsymbol{\mu} = 0$ with maximal power for a single given candidate model shape $\boldsymbol{\mu}_m$ is given by $\mathbf{S}^{-1}(\boldsymbol{\mu}_m - (\boldsymbol{\mu}_m'\mathbf{S}^{-1})/(\mathbf{1}'\mathbf{S}^{-1}\mathbf{1}))$, which

generalizes the formula given in the previous section. Once a dose–response signal is established, one proceeds to the Mod step, fitting the dose–response profile and estimating target doses based on the models identified in the MCP step. There are several ways to fit the dose–response models to the observed data, including approaches based on maximizing the likelihood or the restricted likelihood. Pinheiro et al.^[34] suggested an alternative two-stage approach to the dose–response model fitting based on generalized least squares, where the dose–response model is directly fitted to $\hat{\mu}$ utilizing the inverse of $\hat{S}$ as a weighting matrix. This approach has some computational advantages compared to a full likelihood approach. Although this approach relies on asymptotic results, it has the appeal of being a general purpose application, as it depends only on $\hat{\mu}$ and $\hat{S}$.

DESIGN ASPECTS

There are at least three important design considerations regarding the use of MCP-Mod: 1) selection of the candidate set of models at the design stage; 2) selecting doses to utilize in the trial; and 3) selecting the total sample size of the trial. The material in this section is based on the article by Xun and Bretz^[29] as well as the article by Pinheiro and Bornkamp.^[30]

Selection of the Candidate Set of Models

As a rule of thumb, in many cases, a set of three to seven dose–response shapes corresponding to two to four dose–response models can be appropriate. Note that multiple dose–response shapes might be used for each dose–response model, where the shapes define the contrasts to be used in the MCP step and the models are those to be fitted in the Mod step. There are at least three considerations that play a role in selection of the candidate set of models.

1. *Previous information:* There might exist information for similar compounds in the same indication or the same compound in a different indication. Also an early longitudinal dose–exposure–response model might have been developed on earlier data, which might be used to predict the dose–response curve at the time point of interest.
2. *General experience:* An Emax model should always be included in the candidate model set. A meta-analysis of the shape of dose–response curve, conducted by Thomas et al.,^[8] showed that the sigmoid Emax model can adequately describe the dose–response shape observed in a variety of cases.
3. *Statistical considerations:* If only few test doses are available, it is difficult to fit complex models, such as the sigmoid Emax with four parameters in a trial with three test doses. Such models would thus have to be excluded from the candidate model set and one

would rather rely on more dose–response models with less parameters to obtain an adequate breadth of the candidate set. Another consideration is to evaluate the performance of MCP-Mod under model misspecification. For example, the impact of omitting the true dose–response model from the candidate model set can be negligible if other models in the candidate set can pick up the omitted model. This can be evaluated for the MCP part (impact on power) using explicit calculations and for the Mod part (impact on precision for dose–response and dose estimation) using simulations. Using a broad candidate model set may have an impact on the degree of multiplicity adjustment for the MCP part and increase the critical value. The required sample size to achieve a designated power tends to increase with a broader candidate model set. A similar trade-off exists also in terms of dose–response model fitting, because a broader candidate set will decrease potential bias (in case of model misspecification) but increase the variance of the estimates.

Selection of the Doses to Utilize in the Trial

In many clinical projects, the doses that can be chosen are limited, because only a specific dose strength might be available for administration. Nevertheless, by combining different dose strengths, a variety of doses might be available to be administered. How are specific doses selected to be utilized? As a rule of thumb, four to seven doses and a greater than tenfold dose range (ratio of highest to lowest dose) should be considered (see European Medicines Agency^[35]). Regarding the dose spacing, often log-dose spacing is utilized. The heuristic justification for this is that the variance of drug exposure metrics inside the body increases with the dose (often following a log-normal distribution), which means that the lower dose range needs to be investigated more densely to cover the exposure ranges uniformly. On the other hand, if doses are spaced too close in the upper dose range, they will be too similar in terms of exposure (due to the increase in variance). Motivated by considerations related to safety and also to ensure proper estimation of the steeply increasing part of the dose–response curve, Hamlett et al.^[36] introduce the binary dose spacing design. In this proposal, the designed doses have a twofold, or more generally a p-fold difference, so that, in this design, the lower dose range is also sampled more intensely. An alternative and more formal approach to evaluate different designs is to use optimal design theory based on the candidate dose–response models, as discussed from a practical viewpoint by Pinheiro and Bornkamp.^[30]

Determination of the Total Sample Size

Calculation of the total sample size for the trial can be based on two aspects of MCP-Mod—the MCP-part and

the Mod-part. When calculating the sample size for the MCP-part, the sample size for the study is calculated so that a specific summary power across the different candidate models considered is achieved (e.g., average power or minimum power across all candidate models larger than a specific value). This approach is discussed in detail in the article by Pinheiro et al.^[15] An alternative approach is to base sample size calculations on estimation aspects, for example, estimating the dose–response curve with a given precision or target doses of interest with a given precision. Pinheiro and Bornkamp^[30] discuss different approaches to do this and compare this to the sample sizes obtained, when calculating the sample size based on the MCP part. In general, sample sizes obtained based on modeling considerations tend to be considerably higher than when considering the MCP part alone.

SCOPE OF MCP-Mod

It should be noted that in clinical development, the term “dose” in “dose-finding” refers more generally to a treatment regimen, i.e., the combination of dose and dosing interval. Even more broadly speaking, aspects like the duration of therapy, the route of administration and dosage form (oral, injection, etc.), the time of dosing (after a meal, in the morning, etc.), finding partner drugs or drug–drug interactions, and the population are closely related to the question of dose-finding.

Certainly the MCP-Mod methodology is not applicable to all of these questions. MCP-Mod applies, when the primary focus of the study is the investigation of the population dose–response curve at a specific time point in the context of a phase II study. The method is most informative if it is applied at a time point when the dose–response has stabilized over time and reached its full effect. It applies to parallel group or crossover dose–response studies, and when at least three test doses are utilized, and a placebo (or placebo-like) comparator.

The method does not apply, when the major focus of the study is the determination of the administration frequency and not the dose within given regimens. It is possible to extend MCP-Mod to allow modeling of more than one administration frequency in certain situations. Then additional modeling assumptions would need to be made (e.g., assuming some of the model parameters are shared between regimen and others are different between regimens, see Feller et al.^[37]). MCP-Mod also does not apply, when very different irregular treatment regimens are compared (e.g., some regimens with loading dose versus others without loading dose) or different administration forms are used in the same study e.g., intravenous, subcutaneous injection, etc. When the main study objective is to model the evolvement of the treatment effect over time, the method does not apply, although extensions of MCP-Mod exist that accommodate this when additional modeling

assumptions are being made (e.g., see Pinheiro et al.^[34]). The method should not be used when patients are titrated based on efficacy and/or safety outcomes in a dose titration design. Then, a simple population dose–response analysis will be misleading, as other covariates will not be balanced between the dose groups (due to the lack of randomization). The method also does not apply to dose escalation studies with the purpose of determining the maximum tolerated dose.

Adequate tools to approach many of the questions that are not covered by MCP-Mod (e.g., comparing different irregular treatment regimen, modeling different administration forms, etc.) are more pharmacologically motivated models. In these approaches, typically the relationship of administered dose, blood concentrations, and effect are modeled over time. A great introduction to these models is provided by Källén.^[38]

SOFTWARE IMPLEMENTATION

The most flexible way to implement MCP-Mod is via the DoseFinding R package (<http://CRAN.R-project.org/package=DoseFinding>), which contains extensive functionality both for the design and the analysis of dose-finding studies and examples. Worked examples for design and analysis showing extensive code based on the DoseFinding package are given in the articles by Xun and Bretz^[29] and Pinheiro and Bornkamp.^[30] The commercial software package ADDPLAN-DF contains extensive tools for designing dose-finding studies using MCP-Mod, including complex adaptive dose-finding designs, which are not easily available in the DoseFinding package. The company Cytel has developed PROC MCPMOD as an add-on to SAS that focusses on the analysis of dose-finding studies using MCP-Mod. SAS code to implement MCP-Mod analyses is also available in the article by Bornkamp, Bezlyak, and Bretz^[39].

CONCLUSION

This entry provides an introduction to and a general review of the MCP-Mod methodology. The methodology is described and practical implementation considerations are provided as well as pointers to references containing further information are given.

Measuring Agreement

Lawrence I-Kuei Lin

Baxter Healthcare Corporation, Round Lake, Illinois, U.S.A.

Abstract

The common theme when assessing the acceptability of a new or generic process, methodology, or formulation is the assessment of the agreement between observations and their target values. This entry reviews methods of performing this type of assessment and provides example applications for further illustration of the main concepts.

INTRODUCTION

Consider the problems of assessing the acceptability of a new or generic process, methodology, and/or formulation in areas of laboratory performance, instrument/assay validation or method comparisons, statistical process control, goodness of fit, and individual bioequivalence. The common theme is to assess the agreement between observations (Y) and their target values (X). Target values may be considered random or fixed. Random target values are measured with error. Common random target values are the gold standard measurements, which are the proven and widely acceptable methods. Sometimes we may also be interested in comparing two methods without a designated gold standard method, or in comparing two technicians (times, reagents, etc.) by the same method. Common fixed target values are the expected or known values.

OVERVIEW

Fig. 1 presents a typical situation for assessing agreement. When we plot the observed values on the y axis vs. the target values over a desirable range on the x axis, we would like to see an agreement in that the observations fall closely along the identity line (zero intercept and unit slope). When there is an evidence of disagreement, it is important to address the sources of the disagreement.

Precision and Accuracy

Common basic sources of disagreement would come from a large within-sample variation (imprecision) and/or a shift in the marginal distributions (inaccuracy). Fixing imprecision is a variance reduction exercise, which typically is more cumbersome than fixing inaccuracy. The cause of inaccuracy is most likely a calibration problem. The concepts of precision and accuracy can be seen in Fig. 2.

Traditional Approaches

Traditionally, the assessment of agreement between observed and target values has been by a paired t -test analysis of the data, which can be misleading. Another slightly better approach to the assessment of agreement has been to test the least squares estimates of the linear line against the identity line. We will denote this method as LS01. These two approaches capture only the accuracy information relative to the precision. The potential for obtaining misleading results using these two approaches can be seen in the situations in Fig. 3.^[1]

Another popular traditional method for assessing agreement of observed and target values has been the Pearson correlation coefficient. However, this is a measure of precision only. The potential for obtaining misleading results using this approach can be seen in the situations in Fig. 4.^[1]

Other traditionally used approaches for assessing the agreement of observed and target values have included the coefficient of variation (measure of precision only), the mean square error of the regression analysis (measure of precision only), and the estimate of intercept and slope (measure of accuracy only). Typically, the target values have been assumed fixed in the regression analysis, even when the target values are obviously random.

The best traditional approach for assessing the agreement of observed and target values has been the intraclass correlation coefficient (ICC). The ICC, in its original form,^[2] is the ratio of between the sample variance and the total (within + between) variance under the model of equal marginal distributions. The ICC is intended to only measure precision. However, when the marginal distributions are different (inaccuracy), the ICC is able to capture this deviation information and consider it as imprecision. Several forms of ICC have evolved, but none has distinct and meaningful components of precision and accuracy.

Fig. 1 Assessing the agreement of observed values (new) and target values (gold standard method)

Fig. 2 Precision and accuracy

Fig. 3 Situations when paired t -test or least square test against the identity line (LS01) can be misleading. (a) Rejected by paired t -test and by LS01. (b) Accepted by paired t -test and rejected by LS01. (c) Accepted by paired t -test and by LS01

In addition, the traditional hypothesis testing setting is not appropriate for assessing the agreement of observed and target values. In traditional hypothesis testing, the rejection region (alternative hypothesis) is the region for declaring a difference based on strong evidence presented in the data. Failing to reject the null hypothesis does not

Fig. 4 Situations when Pearson correlation coefficient can be misleading

imply accepting agreement, but implies a lack of evidence for declaring a difference. The proper setting is to reverse the null and the alternative hypotheses, so that the conventional rejection region actually is the region for declaring agreement. Therefore we would reject the null hypothesis of a difference and accept the alternative hypothesis of agreement based on strong evidence presented in the data.^[3–6] Here, a meaningful criterion of an acceptable difference in agreement must be prespecified, and the hypothesis testing is usually one-sided. Actually, the proper hypothesis testing approach is equivalent to computing the one-sided confidence limit for an agreement statistic. If this computed one-sided limit is better than the prespecified criterion, we would accept the alternative hypothesis of agreement. The confidence limit approach is much more straightforward and less confusing than the hypothesis testing approach.

We will now introduce new approaches that evolved in the last 15 years. These new approaches were summarized, studied, and compared by Lin et al.^[7] Most of the following materials have been extracted from the above manuscript.

MODELS

We begin with the most basic model when paired observations (Y and X) are collected.

When Target Values are Random

The joint distribution of Y and X is assumed to have finite second moments with means μ_y and μ_x , variances σ_y^2 and σ_x^2 , and covariance σ_{yx} .

When Target Values are Fixed

$\{y_i|x_i, i = 1, \dots, n\}$ are assumed to be observations in a random sample from the regression model:

$$Y = \beta_0 + \beta_1 X + e_r$$

Here, e_r is the residual error with a mean of zero and a variance σ_e^2 .

METHODS

Mean Square Deviation

This measure evaluates the deviation from the identity line, mean square deviation (MSD) = $E(Y - X)^2$. This is equal to:

1. $\epsilon^2 = (\mu_y - \mu_x)^2 + (\sigma_y^2 + \sigma_x^2 - 2\sigma_{yx})$ when target values are random, or
2. $\epsilon_{|X}^2 = (\mu_{y|\bar{x}} - \bar{x})^2 + s_x^2(1 - \beta_1)^2 + \sigma_e^2$ when target values are fixed

where $\bar{x}$ is the arithmetic average of the X values.

Estimated by sample counterparts (e^2) with a log transformation, $W = \ln(e^2)$ has an asymptotic normal distribution with mean $\ln(e^2)$ and variance:

1. $\sigma_W^2 = 2[1 - (\mu_y - \mu_x)^4/\epsilon^4]/(n - 2)$ when target values are random, or
2. $\sigma_{W|X}^2 = 2[1 - (\epsilon_{|X}^2 - \sigma_e^2)/\epsilon_{|X}^4]/(n - 2)$ when target values are fixed.

In the following, the variance under random ($\sigma_{(.)}^2$) or fixed ($\sigma_{(.)|X}^2$) target values will be presented in similar fashion.

The MSD is difficult to interpret. The intention of the following methods is to put some meaningful interpretation on this basic MSD measurement.

Concordance Correlation Coefficient

The MSD can be standardized such that: 1 = *perfect agreement* ($Y = X$), 0 = *no agreement*, and -1 = *reversed agreement* ($Y = -X$). According to Lin,¹ the concordance correlation coefficient (CCC) is:

$$\rho_c = 1 - \epsilon^2/(\epsilon^2|_{p=0})$$

For ordinal categorical data, CCC degenerates into the weighted kappa suggested by Cohen.^[8,9] The CCC is closely related to the intraclass correlation. The CCC has a meaningful geometric interpretation. It is inversely related to the mean square of the ratio of “within sample total deviation” and “total deviation.” Total deviation is the largest possible deviation among non-negatively correlated samples. Both total deviations in the numerator and the denominator contain the absolute bias. For example, if the within-sample total deviation is 10%, 32%, or 45% of the total deviation, the CCC is 0.99, 0.9, or 0.8, respectively.

The CCC is the product of accuracy and precision. The accuracy measures the closeness of the marginal distributions of Y and X , where 1 = *equal means and variances* and 0 = *no agreement* (far apart). The accuracy can be broken down to measures of location and/or scale shifts, where the

location shift is $v = (\mu_y - \mu_x)/(\sigma_y \sigma_x)^{1/2}$ and the scale shift is $\varpi = \sigma_y/\sigma_x$. Here, accuracy is:

$$\chi_a = 2/(\varpi + 1/\varpi + v^2)$$

Precision measures how close the observations deviate from the best-fit linear line. It is the Pearson correlation coefficient (ρ). ρ^2 has the same scale as accuracy, from 0 (*no agreement*) to 1 (*perfect*).

The CCC estimate (r_c) using sample counterparts by the Z transformation has an asymptotic normal distribution with a mean of $\ln[(1 + \rho_c)/(1 - \rho_c)]/2$ and a variance of:

1. $\sigma_Z^2 = \{(1 - \rho^2)\rho_c^2/[(1 - \rho_c^2)\rho^2] + 2\rho_c^3(1 - \rho_c)v^2/[\rho(1 - \rho_c^2)^2] - \rho_c^4v^4/[2\rho^2(1 - \rho_c^2)^2]\}/(n - 2)$, or
2. $\sigma_{Z|X}^2 = (1 - \rho^2)\rho_c^2/[(n - 2)(1 - \rho_c^2)^2\rho^2] \times [\varpi v^2\rho_c^2 + (1 - \rho_c\rho\varpi)^2 + \varpi^2\rho_c^2(1 - \rho^2)/2]$.

Note that there were typographical errors in Lin.^[1] The above formula for σ_Z^2 is correct.

The accuracy estimate (c_a) using sample counterparts by the logit transformation has an asymptotic normal distribution with a mean of $\ln[\chi_a/(1 - \chi_a)]$ and a variance of:

1. $\sigma_L^2 = [\chi_a^2v^2(\varpi + 1/\varpi - 2\rho) + \chi_a^2(\varpi^2 + 1/\varpi^2 + 2\rho^2)/2 + (1 + \rho^2)(\chi_a v^2 - 1)]/[(n - 2)(1 - \chi_a)^2]$, or
2. $\sigma_{L|X}^2 = [v^2\varpi\chi_a^2(1 - \rho^2) + (1 - \varpi\chi_a)^2(1 - \rho^4)/2]/[(n - 2)(1 - \chi_a)^2]$.

The precision estimate using sample counterparts (r) by the Z transformation has an asymptotic normal distribution with a mean of $\ln[(1 + \rho)/(1 - \rho)]/2$ and a variance of $1/(n - 3)$ when target values are random, or $(1 - \rho^2/2)/(n - 3)$ when target values are fixed.

Total Deviation Index

To examine the agreement from a different perspective, a measure that captures a large proportion (π) of data within a boundary (κ) from target values was considered.^[7,10] Assume that $D = Y - X$ has a normal distribution with a mean of $\mu_d = \mu_y - \mu_x$ and a variance of σ_d^2 . We may find π for a given κ , which is:

$$\pi_\kappa = P(D^2 < \kappa^2) = \chi^2[\kappa^2, 1, \mu_d^2/\sigma_d^2]$$

This measure will be presented later. We may also find κ for a given π , which is:

$$\kappa_\pi = \left\{ \chi^{2(-1)}[\pi, 1, \mu_d^2/\sigma_d^2] \right\}^{1/2}$$

The estimate of this index has intractable asymptotic properties; therefore Lin^[10] suggested the following approximation:

$$\text{TDI}_\pi = \kappa_{\pi^-} = \Phi^{-1}[1 - (1 - \pi)/2]|\epsilon|$$

The approximation is good when $\pi = 0.75$ and $\mu_d^2/\sigma_d^2 \leq 1/2$; $\pi = 0.8$ and $\mu_d^2/\sigma_d^2 \leq 8$; $\pi = 0.85$ and $\mu_d^2/\sigma_d^2 \leq 2$; and $\pi = 0.9$ and $\mu_d^2/\sigma_d^2 \leq 1$, as well as $\pi = 0.95$ and $\mu_d^2/\sigma_d^2 \leq 1/2$. The interpretation of this measure is that approximately $100\pi\%$ of observations are within κ_π from the target values. The TDI_π^2 is proportional to MSD and therefore we may perform inference based on the asymptotic normality of $W = \ln(e^2)$.

Coverage Probability

Now we consider finding the coverage probability (CP) π for a given κ . This is:

1. $\pi_\kappa = P(D^2 < \kappa^2) = \chi^2[\kappa^2, 1, \mu_d^2/\sigma_d^2]$ when target values are random, or
2. $\pi_{\kappa|X} = \sum \pi_{\kappa i}/n$, where $\pi_{\kappa i} = \chi^2[\kappa^2, 1, [\beta_0 + (\beta_1 - 1)x_i/\sigma_e]^2]$ when targeted values are fixed.

The estimate using sample counterparts (p_κ) by the logit transformation has an asymptotic normal distribution with a mean of $\ln[\pi_\kappa/(1 - \pi_\kappa)]$ and a variance of:

1. $\sigma_\pi^2 = \{[\kappa_{+\mu\sigma}\phi(-\kappa_{+\mu\sigma}) + \kappa_{-\mu\sigma}\phi(\kappa_{-\mu\sigma})]^2/(2n) + [\phi(-\kappa_{+\mu\sigma}) - \phi(\kappa_{-\mu\sigma})]^2/[(n-3)(1 - \pi_\kappa)^2\pi_\kappa^2]\}$, or
2. $\sigma_{\pi|X}^2 = [C_0^2/n^2 + (C_0\bar{x} - C_1)^2/(n^2s_x^2) + C_2^2/(2n^2)]/[(n-3)(1 - \pi_\kappa)^2\pi_\kappa^2]$

where

$$\begin{aligned}\kappa_{+\mu\sigma} &= (\kappa + \mu_d)/\sigma_d, \kappa_{-\mu\sigma} = (\kappa - \mu_d)/\sigma_d. \\ \kappa_{+\mu\beta\sigma i} &= [\kappa + \beta_0 + (\beta_1 - 1)x_i]/\sigma_e. \\ \kappa_{-\mu\beta\sigma i} &= [\kappa - \beta_0 - (\beta_1 - 1)x_i]/\sigma_e. \\ C_0 &= \sum[\phi(-\kappa_{+\mu\beta\sigma i}) - \phi(\kappa_{-\mu\beta\sigma i})]. \\ C_1 &= \sum[\phi(-\kappa_{+\mu\beta\sigma i}) - \phi(\kappa_{-\mu\beta\sigma i})]x_i. \\ C_2 &= \sum[\kappa_{+\mu\beta\sigma i}\phi(-\kappa_{+\mu\beta\sigma i}) + \kappa_{-\mu\beta\sigma i}\phi(\kappa_{-\mu\beta\sigma i})].\end{aligned}$$

Proportional Error Case

When Y and X are positively valued variables and the errors are proportional to X , we assume that $\ln(Y)$ and $\ln(X)$ have a bivariate normal distribution. Let $100\theta\%$ be the percent change in Y and X , then:

$$\begin{aligned}\pi_\theta &= P[1/(1 + \theta) < Y/X < (1 + \theta)] \\ &= P[|\ln(Y) - \ln(X)| < \ln(1 + \theta)]\end{aligned}$$

Let $D = \ln(Y) - \ln(X)$ and $\kappa = \ln(1 + \theta)$ then $\theta = 100[\exp(\kappa) - 1]\%$. This $100\theta\%$ is called the $\text{TDI}_\pi\%$. In the case of proportional errors, the CCC, precision, and accuracy should be computed from log-transformed data. The same is applicable when target values are fixed.

Simulation Results

The parameters discussed above can be replaced with their sample estimates that are consistent estimators, usually the moments estimates, in order to perform inferences. A comprehensive simulation study was conducted^[7] to study the small sample properties of CCC, precision, accuracy, total deviation index (TDI), and CP. The results showed excellent agreement with theoretical values from normal samples even when $n = 15$. However, these estimates are not expected to be robust against outliers and/or large deviations from normality (or log normal). The robustness issues of the CCC have been addressed in King and Chinchilli.^[11]

Asymptotic Power

In assessing agreement, the null and the alternative hypotheses should be reversed. The conventional rejection region actually is the region of declaring agreement (one-sided). Asymptotic power and sample size calculation should proceed by the above principle. These powers of CCC, TDI, and CP were compared.⁷ The results showed that the TDI and CP estimates have similar power, and are superior to CCC. Therefore for inference, TDI and CP are superior to CCC. The CCC, precision, and accuracy remain as very useful descriptive tools.

EXAMPLES

Methods Comparison Example (Random Target Values, Constant Error)

The DCLHb is a treatment solution containing oxygen-carrying hemoglobin. The DCLHb level in a patient's serum is routinely measured by the Sigma method. The HemoCue method was modified to reproduce the DCLHb values of the Sigma method. Serum samples from 299 patients over a 50–2000 mg/dL range were collected. The DCLHb values of each sample were measured by both methods. The client wanted to be able to state with 95% confidence that the within-sample total deviation would be less than 15% of the total deviation. This means that the allowable CCC is $1 - 0.15^2 = 0.9775$. The client also wanted to state that 90% of the HemoCue observations would be within 150 mg/dL from the targeted Sigma values. This means that the allowable $\text{TDI}_{0.9}$ is 150 mg/dL, or that the allowable CP_{150} is 0.9.

The results are presented in Fig. 5. The plot indicates that the within-sample error is relatively constant across the clinical range. The plot also indicates that the HemoCue accuracy is excellent and that the precision is adequate.

The CCC estimate is 0.987, which means that the within-sample total deviation is about 11.6% of the total

Fig. 5 HemoCue (vertical) vs. Sigma (horizontal) [mg/dL]. $CC = 0.987$ ($0.984 > 0.9775$); $r^2 = 0.974$ (0.968); $c_a = 0.9999$ (0.9989); $TDI_{0.9} = 127.5$ ($136.4 < 150$); $CP_{150} = 0.946$ ($0.928 > 0.9$)

deviation. The CCC one-sided lower confidence limit is 0.984, which is greater than 0.9775. The precision squared estimate is 0.974 with a one-sided lower confidence limit of 0.968. The accuracy estimate is 0.9999 with a one-sided lower confidence limit of 0.9989. The $TDI_{0.9}$ estimate is 127.5 mg/dL, which means that 90% of HemoCue observations were within 127.5 mg/dL of their target values. The one-sided upper confidence limit for $TDI_{0.9}$ is 136.4 mg/dL, which is less than 150 mg/dL. Finally, the CP_{150} estimate is 0.946, which means that 94.6% of HemoCue observations are within 150 mg/dL of their target values. The one-sided lower confidence limit for CP_{150} is 0.928, which is greater than 0.9. The agreement between HemoCue and Sigma is acceptable with excellent accuracy and adequate precision. The relative bias squared is estimated to be 0.003, so the approximation of TDI should be excellent.

Assay Validation Example (Fixed Target Values, Proportional Error)

FVIII is a clotting agent in plasma. The FVIII assay uses a marker with varying dilutions of known FVIII activities to form a standard curve. The standard curve started at 1:5 or 1:10, and serial dilutions were prepared until they reached the target values. Target values were 3%, 8%, 38%, 91%, and 108%. Six samples were assayed per target value. The error was expected to be proportional due largely to dilutions. The client wanted to be able to state with 95% confidence that the within-sample total deviation would be less than 15% of the total deviation. This means that the allowable CCC is $1 - 0.15^2 = 0.9775$. The client also wanted to be able to state that 80% of FVIII observations (%) would be within 50% from target values percent (percentage of percentage). This means that the allowable $TDI_{0.8}$ is 50%, or that the allowable $CP_{50\%}$ is 0.8.

Fig. 6 presents the results started at 1:5 and at 1:10 for the plots of observed FVIII assay results vs. targeted values in $\log_2$ scale. Note that in Fig. 6a, four 3% and two 2% were observed at the target value of 3%, and circles at the target value of 8% represent duplicate readings of 8%, 9%, and 10%. Duplicate readings of 45% were observed at target values of 38%. Also note that in Fig. 6b, four 5% and two 4% were observed at the target value of 3%. Three 11% and two 12% were observed at the target value of 8%. Duplicate readings of 49% were observed at target values of 38%. Duplicate readings of 124% were observed at target values of 91%. The plots indicate that the within-sample error was relatively constant across the target values in log scale. The precision was good for both assays started at 1:5 and at 1:10, but the accuracy was not as good for the assay started at 1:10.

For the results started at 1:5, the CCC was estimated to be 0.992, which means that the within-sample total deviation is about 9.1% of the total deviation. The one-sided lower confidence limit was 0.987, which was greater than 0.9775. The precision squared was estimated to be 0.988 with a one-sided lower confidence limit of 0.982. The accuracy was estimated to be 0.998 with a one-sided lower confidence limit of 0.994. The $TDI_{0.8}$ was estimated to be 27.3%, which means that 80% of observations were within 27.3% change from target values (percentage of percentage values). The one-sided upper confidence limit was 35.0%, which is less than 50%. Finally, the $CP_{50\%}$ was estimated to be 0.965, which means that 96.5% of observations were within 50% change from target values. The one-sided lower confidence limit was 0.892, which was greater than 0.8. The agreement between the FVIII assay and the actual concentration was acceptable with good precision and accuracy. The relative bias squared was estimated to be 0.009, so that the approximation of TDI should be excellent.

For the results started at 1:10, the CCC was estimated to be 0.967, which means that the within-sample total deviation is about 18.2% of the total deviation. The one-sided lower confidence limit was 0.958, which is less than 0.9775. The precision squared was estimated to be 0.989 with a one-sided lower confidence limit of 0.983. The accuracy was estimated to be 0.972 with a one-sided lower confidence limit of 0.964. The $TDI_{0.8}$ was estimated to be 58.9%, which means that 80% of observations were within 58.9% change from target percentage values. The one-sided upper confidence limit was 69.0%, which is greater than 50%. Finally, the $CP_{50\%}$ was estimated to be 0.702, which means that 70.2% of observations were within 50% change from target values. The one-sided lower confidence limit was 0.590, which was less than 0.8. The agreement between the FVIII assay and the actual concentration had good precision but was not acceptable because of mediocre accuracy. The relative bias squared was estimated to be 3.747, so that the approximation of TDI should be acceptable.

Fig. 6 FVIII assay (vertical) vs. actual values (horizontal) [%] (in $\log_2$ scale). (a) Started at 1:5: CCC = 0.992 (0.987 > 0.9775); $r^2 = 0.988$ (0.982); $c_a = 0.998$ (0.994); $\text{TDI}_{0.8}\%$ = 27.3% (35.0% < 50%); $\text{CP}_{50\%} = 0.965$ (0.892 > 0.8). (b) Started at 1:10: CCC = 0.967 (0.958 < 0.9775); $r^2 = 0.989$ (0.983); $c_a = 0.972$ (0.964); $\text{TDI}_{0.8}\%$ = 58.9% (69.0% > 50%); $\text{CP}_{50\%} = 0.702$ (0.590 < 0.8)

CONCLUSION

Under normality assumptions, the CCC, TDI (MSD), and CP basically measure the same information from different perspectives. The CCC, precision, accuracy, and ICC largely depend on the study range (intersample variation). Comparisons among any of these are valid only with similar study ranges. When the study range is fixed and meaningful, the CCC, precision, and accuracy offer meaningful geometric interpretations. The TDI and CP offer the most intuitively clear interpretation and have better power for inference, but they do not have precision and accuracy components.

For computing the above agreement statistics and generating an agreement plot, a SAS macro is available (<http://www.uic.edu/~hedayat/>), which can be downloaded by users.

RECENT DEVELOPMENTS AND FUTURE STUDIES

Chinchilli et al.^[12] addressed the topic regarding repeated measures CCC. Vonesh et al.^[13] and Vonesh and Chinchilli^[14] addressed the topic regarding the goodness of fit using CCC. King and Chinchilli^[11] addressed the CCC among more than two methods and robust CCC. Barnhart and Williamson^[15] used a very general approach to model

the CCC using generalized estimation equations (GEE). Our ultimate goal is to work on robust CCC, accuracy, precision, CP, and TDI via GEE. This will then be applicable to more general cases involving repeated measures of Y and X with covariates. Therefore it will be applicable to the individual bioequivalence problem (target values are always random), where repeated measures of test and reference drugs from a patient with covariates are taken.

MedDRA: Impact on Pharmaceutical Development

Keya T. Pitts

Bristol-Myers Squibb Company, Princeton, New Jersey, U.S.A.

Abstract

The Medical Dictionary for Regulatory Activities (MedDRA) was selected in 1999 by the International Conference on Harmonization (ICH) as the international standard for the encoding of medical terms captured in both the pre- and post-approval phases of drug development. This entry discusses the creation of the MedDRA as well as its reception and use in the pharmaceutical field.

Keywords: Adverse events; Clinical trials; Coding MedDRA; Postmarketing; Versioning.

INTRODUCTION

The Medical Dictionary for Regulatory Activities (MedDRA)^a was selected in 1999 by the International Conference on Harmonization (ICH) as the international standard for the encoding of medical terms captured in both the pre- and post-approval phases of drug development. This new coding terminology was not like the coding dictionaries of the past; with this new dictionary came a previously unobserved set of both advantages and challenges. The MedDRA Maintenance and Support Services Organization (MSSO), tendered by the International Federation of Pharmaceutical Manufacturers and Associations (IFPMA), is charged with the administration of the terminology, and provision of guidance to its subscribers in its appropriate and intended application to patient data for the purposes of standardized regulatory reporting to health authorities.

Current State of the MedDRA Structure

Since its formal commercial introduction in 1999, MedDRA remains granular, containing more than 85,000 terms across the encoding levels (Lowest Level Terms (LLTs) and Preferred Terms (PTs)). The term level used for encoding may vary with the sponsor or manufacturer's coding philosophy. The Lowest Level Term consists of synonyms, culturally unique terms, and lexical variants of the corresponding Preferred Term. The Preferred Term is the level at which MedDRA establishes individual unique medical concepts and specific medical conditions. The High Level Term (HLT) is somewhat broader, and usually groups terms related to a general condition. Above the HLT is the High Level Group Term (HLGT), which further collectively

presents associated concepts into broadly presented groups. Finally, at the peak of the hierarchy is the System Organ Class (SOC). The scope of the SOC in MedDRA have not essentially changed since its commercial release, remaining 26 in the number of groupings, which has been important in maintaining consistency over time for sponsors that have utilized or referenced MedDRA in adverse event presentation within package labeling.

Although the number of term selections available at the Lowest Level and Preferred Term levels has grown considerably, the uppermost levels have been somewhat more stable. These intermediate levels may also be used by sponsors in meaningful data presentation and analyses, although the Preferred Term may be the more common level used in presentation of adverse event concepts in the labeling.

Some of the issues that were observed with the use of past terminologies continue to exist with this one dictionary, but now involve the use of different versions, as MedDRA is released twice-yearly (at the time of the writing this article). Using different terminologies at various stages in a product's life complicates data retrieval and analysis, making it difficult to cross-reference data. In the past, safety data had frequently been classified for pre-registration clinical trials using ICD terminology and for post-marketing surveillance using J-ART, WHO-ART, or COSTART. Furthermore, using different terminologies in separate geographic regions impaired international communication and necessitated the conversion of data from one terminology to another. This data conversion had the potential to cause time delays, and loss or distortion of data. In particular, these problems affected multinational pharmaceutical companies whose subsidiaries used multiple terminologies to fulfill the different local data submission requirements of regulators. The use of multiple terminologies also affected communication between companies and clinical research organizations.^[1]

MedDRA terms each have a unique numeric identifier; however, the field is non-expressive, meaning that no

^aMedDRA® is a registered trademark of the International Federation of Pharmaceutical Manufacturers and Associations (IFPMA).

information can be further derived from it. Because the terms at the preferred level are repeated again at the lowest level for data entry purposes, these terms will have the same code or identifier for each level, thus identifying them as preferred terms, but providing no information such as related body system(s) or other groupings. Use of the numeric code became increasingly important as sponsors had to manage the process of versioning in the creation of the Integrated Summary of Safety for marketing authorizations. Versioning approaches will be discussed in the next section.

MedDRA-Encoded Data and the Concept of Versioning

As companies began to utilize MedDRA in the conduct of clinical trials to support Investigational New Drug (IND) or Clinical Trial Applications (CTAs), and New Drug Applications (NDAs) or Marketing Authorizations (MAs) for their products, a learning curve had to be mastered. With MedDRA commercially released twice per year, the issue of versioning in clinical trials had to be addressed. The MedDRA Maintenance and Support Services Organization (MSSO), responsible for maintaining the terminology for its subscribers, published recommendations for industry on how to manage versioning for clinical trials and the investigational phases of product development.^[2] These approaches served to provide companies some basic guidance in determining which versioning strategy best suited their processes, while regulators sought to also navigate the same waters and figure out the regulatory perspectives on clinical data presentation with MedDRA.

The six recommendations comprised every possible approach that could reasonably be applied for clinical trial data, given that trials are conducted over time and many different dictionary versions would be impacted.

The MSSO's **Option 1**—to select one version of MedDRA at the beginning of a project and continue to utilize for the life of the project through application submission—represents a seemingly uncomplicated approach to versioning. Benefits include ease in coding review across studies, report generation, and ease in development of data management, coding and statistical plans across studies. Some of the challenges with applying this strategy include not gaining the advantages of the evolving terminology and structural changes as well as data reconciliation between the clinical and safety databases (when companies opt to have their post-marketing pharmacovigilance units manage serious adverse event reporting to health authorities).

Option 2 presented a slight variant to option 1, the difference mainly being that users would begin with one version and use throughout, but once all submission studies have been completed in that version, all data would be upversioned to the version of MedDRA current at that point in time, to analyze and report. This brings a current perspective to the data, and will benefit companies with

detection of any potential issues that may have obscured through earlier version encoding. However, this does also potentially lengthen the time to submission because the upversioning work needs to be accounted for at the end of the process but prior to analyses, and addressing the changes from individual clinical study reports to the Integrated Safety Summary (ISS) data presentation.

Option 3 was another variant, allowing sponsors to begin each study with the version of MedDRA current at that point in time, and again upversion all study data at the time prior to summary analysis. This option would slowly introduce any changes in the observed safety profile through changes in coding from study to study. As the dictionary itself improves over time, these advantages would now be made available to users for more precise review. When the time comes to upversion all the data for the ISS, there is a small decrease in time needed, and there should be fewer unforeseen issues, previously undetected through coding.

The next option is not known by the author to be widely implemented—**Option 4** describes an approach that does not require the sponsor to encode individual clinical trial data as it is received but rather to hold all coding to be performed at the end of a study. Gains would be made in coding consistency with having it done at one time. Although this may seem like an approach to minimize the impact of versioning, it loads the work to be done at the back end of a study, and would not support accurate signal detection and safety risk management during the course of study conduct.

Option 5 is also a variant of Option 1, in that sponsors may initiate a study with a given version of MedDRA and *optionally* recode in a more recent version of MedDRA at the end of the study, but they must definitely upversion all data at the time prior to summary analysis. This would take advantage of the use of supplemental terms, or terms that may have been requested by subscribers for an upcoming release but are not yet available at the time of coding. Companies may choose to record the approved supplemental term in their database, but until the next version is released, the term technically is not associated with a version of MedDRA; or, they can enter a best-available choice from the version they are using and in either situation, exercise the option to recode at the end of the study before generation of the final clinical study report. Longer studies would gain from this approach and provide more beneficial analyses of data.

The final option is **Option 6**, which involves versioning of the trial data within a program with each commercial release of MedDRA. All trial data would be updated with each version and would provide consistency for reporting. Using this approach removes reconciliation issues with post-market safety data since post-market data will usually tend to be captured, coded, and reported with each new current version of MedDRA. This strategy does require some additional resourcing with respect to coding activity and more frequent maintenance of coding guidelines and

conventions, but provides a consistently current perspective of the data.

Pharmacovigilance functions in the post-marketing arena were predominantly first to utilize MedDRA for data capture and reporting expedited or periodic reports. Within industry and regulatory health authorities, post-marketing drug safety and pharmacovigilance were heavily represented on the international working groups that championed its evolution and implementation. With the regards to the versioning approach for safety and pharmacovigilance, those regulators that require reporting in MedDRA facilitated the versioning option for implementation with mandates of timeframes and version requirements in certain regions. As of the writing of this article, the European Commission and the Ministry of Health, Labour and Welfare (MHLW) for Japan both require reporting of spontaneous adverse event reporting to be done in MedDRA.^[3,4] The U.S. Food and Drug Administration (FDA) recommended MedDRA's use via draft and final guidances in both post-marketing reporting and NDA submissions; MedDRA was indicated in a Proposed Rule in 2003, but at this time, it is not mandated.^[5] The regulators mentioned have converted their respective databases to MedDRA and do have varying strategies and approaches to version control.

Aggregate Data Analysis and Presentation Using MedDRA

As the industry began to determine strategies for coding and versioning with MedDRA, the issue of data presentation also had to be addressed. MedDRA, being a much granular dictionary, required sponsors to really understand the terminology's structure and how that would impact data analysis and presentation. The quality of the "Preferred Term" from legacy terminology and previously used in analyses and listings would change significantly with the use of MedDRA. The MedDRA Preferred Term reflects a unique medical concept, and with over 18,400 preferred terms in version 12.0, the listings of coded data presented at the same level in MedDRA and, for a single study, will increase dramatically. As the System Organ Class (SOC) level is most like a "Body System" used in legacy dictionaries, and the MedDRA Preferred Term is the level of the medical concept, they currently remain the typical levels reflected within summary data tabulations and package labeling. The next sections will address how data presentation has been formally addressed by international working groups, industry, and the MedDRA maintenance organization.

Investigational Data Presentation

Requirements for data presentation for products under investigation (prior to market authorization will vary based upon the regional regulations. There will be requirements

for which cases will be presented (e.g., serious and associated adverse events), and grouping by SOC with the PTs observed has essentially continued to remain the industry standard, as recommended by internationally recognized pharmaceutical working groups.^[6]

Where there are many terms to be listed, inclusion of the intermediary MedDRA hierarchy grouping terms may prove clinically beneficial. As the MedDRA Preferred Term has been somewhat diluted compared to the "Preferred Term" of legacy terminologies, the High Level Term or High Level Group Term may aid to articulate the adverse event observations from a study as more meaningful medical concepts.

Presentation of the MedDRA concepts at any level of the hierarchy would not normally impact any of the typical summary tabulations that are generated, with the exception of a summary tabulation by age group. For pediatric studies, perhaps done as a post-marketing commitment that may be required in some regions, studies may comprise pediatric subjects across age groups. In this situation, utilizing the intermediate levels for data presentation as well as the Preferred Term level, which include concepts like HLGT Neonatal respiratory disorders and HLT Neonatal gastrointestinal disorders, will group terms specific to the neonatal period of life, away from concepts, to enable identification of such events. Of course, proper encoding of the reported adverse event term is required to ensure that it is grouped with its accurate grouping term. This provides additional benefit when the original reported information or demographic variables are not included in the specific presentation.

MedDRA aligns a medical concept under its most relevant SOC, but secondarily links concepts to other SOC's that are also related. Thus, industry initially struggled with how to apply the secondary SOC's in analysis and presentation for premarketing applications. The MedDRA MSSO subsequently developed a white paper addressing the issue, in the MedDRA Data Retrieval and Presentation: Points to Consider Guidance has been provided that recommends sponsors present the data by primary SOC as a standard in both marketing authorizations and the proposed package labeling for consistency across drug classes; then, if desired or requested, data may be displayed in focused searches or analyses utilizing secondary term assignments.^[7]

In the realm of product labeling, MedDRA is only known to be mandated for use in the presentation (i.e., labeling) of adverse drug reactions/events by the European Commission. The intermediate levels are recommended for inclusion in the Summary of Product Characteristics, if they further assist to present adverse drug reactions in a more meaningful way to the prescribing professional and patient.

Post-marketing Data Presentation

The use of MedDRA in post-marketing data presentation has been addressed within guidance documents proposed and finalized by the International Conference on Harmonization

(ICH). Although at the time of finalization of the E2C guidance on Periodic Safety Update Reporting, MedDRA had not yet been agreed, but a standardized coding terminology was recommended by the ICH for the presentation of adverse drug reaction data within a product's Core Safety Information section of the Company Core Data Sheet (CCDS), and for data presentation in the line listings within the Periodic Safety Update Report (PSUR).^[8] MedDRA was, of course, later agreed in the ICH E2B R3 Electronic Transmission of Individual Case Safety Reports guidance.^[9] The PSUR requires data to be presented in increments of time; and as MedDRA is upversioned with each new release twice a year, stating the version number is essential for regulators to fully evaluate the data in its context.

Within the PSUR, tabulations of adverse events/adverse drug reactions are requested to be presented by the body system using the standardized coded term rather than the verbatim. Given that product labeling may reflect intermediate level MedDRA terms, the periodic data may be further summarized in the PSUR using the same concepts for consistency but always reflecting the version to help interpret, as the regulators who may receive the report will be working with varying MedDRA versions.

Primarily in support of pharmacovigilance, the original concept behind Special Search Categories (SSCs) in the use of MedDRA was to aid MedDRA subscribers in reviewing collection of MedDRA-encoded data for clusters of specific syndrome terms across system organ classes that may not be readily observed with manual review of the data. As the SSCs initially developed were determined to not be of much benefit to industry and regulators alike, the Council for International Organizations of Medical Sciences (CIOMS) formed a working group comprised of regulators, prominent industry safety leaders, representatives of leading health organizations, such as the World Health Organization (WHO), and the MedDRA MSSO. The group's purpose was to develop rational use of the MedDRA Terminology for Drug Safety Database Searches and was established in May 2002.^[10] The group formulated what are now known as Standard MedDRA Queries (SMQs) that can be utilized by regulatory authorities, scientific institutions, and pharmaceutical companies worldwide to enable consistent and appropriate use of SMQs in drug surveillance.

As of MedDRA v12.0, there were 74 SMQs in production use that replaced the SSCs. Many others continue under development by the MedDRA MSSO in conjunction with the CIOMS SMQ working group, with recommendations always made possible through subscriber requests. Just as with dictionary content, the SMQs are maintained with respect to currency, relevance, and clinical accuracy.

SMQs are designed to follow an algorithm that, when applied, will look at adverse event data within a case and determine if the report's encoded terms coincide with the criteria within the SMQ to reflect the SMQ's topic, and cases may be weighted or ranked, according to how the

subscriber applies the SMQ and other criteria that may also be relevant. SMQs collate related Preferred Terms across the terminology that may be indicative of a sign and/or symptom of a specific condition or syndrome. The SMQ will include conditions, laboratory test results, and surgical procedures, where relevant. The concepts currently reflected as SMQ topics are of greater relevance to safety issues in pharmaceutical development.

Companies may opt to apply a relevant SMQ in response to a regulator's inquiry on a specific topic or issue, which enables reproducibility of results for both parties, with consideration given to the version and stability of the underlying data.

As subscribers become more comfortable with the application of the SMQ for post-marketing pharmacovigilance, the benefit of their application to assist with detection of potential safety issues, prior to a marketing application's submission, will begin to emerge.

Data Collection Principles Affecting Analyses

Be it within clinical development or the post-marketing environment, data collection techniques and guidelines will affect how the data is interpreted in coding and later analyzed. As was mentioned earlier, not only does demographic information at times affect how data is encoded, grouped, and analyzed, but as well, details that can be collected about the adverse event information will affect it. The route of administration for the investigational or marketed product can pose a factor in adverse event capture and collection. Administration site reactions are grouped separately from the body system events, in the General and Administration Site Conditions SOC (Fig. 1); however, they will have a secondary link, through MedDRA's multi-axiality, to the underlying body system (Fig. 2).

These types of characteristics should be taken into consideration in order to obtain more concise data interpretation for a clinical trial or post-marketing data. If data

Fig. 2 Display of secondary MedDRA hierarchy for site reaction concepts. PTs Application site hypersensitivity and Infusion site hypersensitivity are linked secondarily to the Immune SOC

collected clearly denotes if an event occurred at the site of administration for the product, it will be more accurately encoded under the proper PT, such as those reflected in Fig. 2. Without this information collected from the subject or patient, it may have been presumed to have a different etiology or causality. For example, with a product that is administered via injection, capturing an event as “injection site-related” when appropriate is ultimately important for accurate display of observed adverse events within the prescribing information and medication guide.

CONCLUSION

As the Medical Dictionary for Regulatory Activities has been in commercial use by industry and regulators alike for eight years now, the benefits and challenges of adapting to MedDRA have surfaced. The MedDRA MSSO, in conjunction with its user groups and industry expert panels, has worked continuously to address those challenges, such as versioning, utility, and validity of MedDRA’s multi-axiality in data analyses.

The issue of versioning proved to be one that affected the pre- and post-marketing arenas in vastly different ways. With divisions of health authorities attaining differing levels of MedDRA readiness, given it was driven predominantly by the post-approval division of the major authorities. Post-marketing data was quickly required to be submitted encoded in MedDRA in some regions, and subsequently requirements were set for the timely use of MedDRA versions for some level of consistency with the regulators receiving the data. However, not all regulators in all regions set requirements for use of MedDRA, let alone a specific version with which data should be reported.

With the Proposed Rule on post-marketing safety data issued by the FDA in 2003, it was evident that the US was planning to require the use of MedDRA, but as part of a

much larger set of proposed regulations, the use of MedDRA still has yet to be mandated in U.S. regulatory reporting.

In the environment of pre-approval data, the European Commission has required the use of MedDRA in submissions, but the United States has not yet finalized a regulation on a position on MedDRA use in investigational and marketing applications and product labeling.^[11]

Subscribers have the MedDRA MSSO and industry expert working groups to look to for guidance in the management of MedDRA with respect to not only coding, but versioning, data analysis, and presentation. It is helpful to know that the health authorities also faced the same issues, and thoughtfully collaborated with industry to develop feasible and effective approaches to these issues. The key overarching benefit to the use of MedDRA include standardization of the patient safety data collected between pharmacovigilance and development functions, from company to company in safety data exchange, and among regulators and industry. To fully realize this benefit, standardized approaches to how versioning of MedDRA should be managed should be consistent across the regions for reporting both investigational and post-marketing data; as well, industry should aim to continue to partner with the regulators in evaluating the most effective and accurate standards for analysis and presentation of MedDRA-encoded data, for the ultimate benefit of delivering safe yet effective medication options to the patient.

Abstract

Medical devices comprise a staggering array of products that include everything from diagnostic tests and monitors, to therapeutic machines and instruments and replacements for failing body parts. This entry focuses on statistical issues in medical devices, touching on methodological discussions for implants, statistical challenges of diagnostic devices, and the crucial role of prior information in the design of medical devices.

Keywords: Diagnostic devices; Masking; Medical devices; Placebo; PMA; Surrogates.

INTRODUCTION

Medical devices comprise a staggering array of products that include everything from diagnostic tests and monitors, to therapeutic machines and instruments and replacements for failing body parts. They include artificial skin, hips, knees, and breast implants; apnea and cardiac monitors; glucose and cholesterol tests; magnetic resonance imaging machines and ultrasound bone sonometers; intraocular lenses and ophthalmic lasers; manual and robotic surgical instruments; and gloves. They also include prostate-screening antigen (PSA) tests for prostate cancer detection and monitoring, cardiac defibrillators, left ventricular assist devices, and the coronary stents that are revolutionizing interventional cardiology.

Within the Food and Drug Administration (FDA), the Center for Devices and Radiological Health (CDRH) is charged with the regulation of medical devices in the United States. For regulatory purposes, a *device* is defined by law as “an instrument, apparatus, implement, machine, contrivance, implant, in vitro reagent, or other similar or related article, including any component, part, accessory, which is (i) recognized in the Official National Formulary, or the United States Pharmacopoeia, or any supplement to them, (ii) intended for use in the diagnosis of disease or other conditions, or in the cure, mitigation, treatment, or prevention of disease, in man or other animals, or (iii) intended to affect the structure, or any function of the body of man or other animals, and which does not achieve its primary intended purposes through chemical action within or on the body of man or other animal and which is not dependent upon being metabolized for the achievement of its primary intended purposes.”^[1] A more practical and somewhat simpler definition for many people is one of exclusions, namely, any medical item that is *not* a drug and *not* a biological product.

This paper will discuss the statistical issues in medical devices in four subsequent sections. The section “Regulation of Medical Devices” concerns the regulation of medical devices. The section “Design Issues in Non-diagnostic Medical Device Studies” concerns non-diagnostic devices and includes methodological discussions for implants (knee, hip, breast prosthesis) as well as therapeutic devices such as external defibrillators or lasers for eye surgery. The section “Diagnostic Devices” will treat the unique statistical challenges that diagnostic devices pose. Diagnostic medical devices can be used in screening, diagnosing, or monitoring of patients; such products include genetic markers for cancer, PSA tests, MRI machines, bone densitometers, mammography machines, glucose meters for home testing as well as the wide variety of clinical laboratory tests such as ones for creatine kinase, chlamydia, and pregnancy. The section “Bayesian Approach in Evaluating Medical Devices” will address the crucial role that prior information can play in the design and analysis of medical device clinical trials. The section “Statistical Issues in the Postmarket” and the “Conclusion” section will address postmarketing issues and the future of medical device evaluation, respectively.

REGULATION OF MEDICAL DEVICES

Regulatory History in the United States

In terms of regulatory history in the United States, 1976 marked the beginning of medical device regulation in its own right. The 1976 Medical Device Amendments to the Food, Drug, and Cosmetic (FD&C) Act gave the FDA explicit authority to evaluate safety and effectiveness of medical devices. These amendments also recognized the special nature of medical devices and defined specific

provisions including the Premarket Approval (PMA) and the Premarket Notification pathways to market. To carry out these provisions, FDA created the Bureau of Medical Devices. In 1982, this fledgling bureau merged with the Bureau of Radiological Health to form CDRH, and in 1990, 1992, and 1997, Congress passed further amendments to refine the regulation of medical devices as well as other FDA-regulated products. Headquartered in Silver Spring, MD, CDRH^[2] now has a staff of about 1200. Statistical programs in the Center are organizationally located in the Division of Biostatistics, which has a staff of 55.

Regulation of Medical Devices vs. Pharmaceutical Drugs in the United States

In comparison to pharmaceutical drugs, there are some similarities and differences in how medical devices are regulated. There are often preclinical studies, sometimes using animal models, for medical devices, but the issue is usually not toxicity as in pharmaceuticals. In many instances, the mechanism of action of even a new device technology is well understood, physical and local as opposed to chemical and systemic. Most device product lines evolve substantially through a series of changes. Whereas changes to a drug formulation can drastically change the safety and efficacy profiles, small changes to a device may have little or no effect on either safety or effectiveness. Unlike the pharmaceutical industry, which consists of relatively few very large companies, the medical device industry has a large number of companies (over 10,000). While a few of these are quite large, the median size of medical device firms is under 50 people. The regulation of medical devices in the United States reflects the above differences. Whereas the standard for pharmaceutical drug regulation is two well-controlled Phase III trials that demonstrate safety and efficacy, the standard for medical devices is different depending on the regulatory pathways described below, but is usually not more than one confirmatory, well-controlled, multicenter study.^[3–5]

Premarket Approval Applications

The PMA process is the most rigorous regulatory pathway to market a new device technology. By law, the decision to approve or disapprove a PMA application must “rely upon valid scientific evidence to determine whether there is reasonable assurance that the device is safe and effective.” Again, by law, “Valid scientific evidence is evidence from well-controlled studies, partially controlled studies and objective trials without matched controls, well-documented case histories conducted by qualified experts that there is a reasonable assurance of safety and effectiveness ...”⁶ These criteria differ from the regulatory standards set by law for pharmaceutical drugs and biological products in the United States and these differences lead to a more varied approach in the nature of studies and data

required to support market approval for devices. As part of the PMA process, the FDA seeks advice from outside experts who serve on 18 Advisory Panels of the Medical Devices Advisory Committee. For more information about the Advisory Committee structure for FDA, see Ref. [7].

Premarket Notifications (510(k))

A pathway to market for medical devices that has no direct analog in drug regulation is Premarket Notification, often referred to as the 510(k) process (from FD&C provision). In general terms, this process allows manufacturers to notify the FDA that they intend to market a product as a “me too” device. The manufacturer must establish that the new device is “substantially equivalent” to a predicate device, i.e., a device marketed at the time of the 1976 Medical Device Amendments. If the FDA agrees that the device is substantially equivalent, the new device is then cleared for marketing in the United States.

Investigational Device Exemption

Usually, to demonstrate that a new device is safe and effective and, sometimes, to show that it is substantially equivalent to another device, the new device must be studied in humans. To protect patients participating in studies where there is significant risk, a company or individual researcher must apply for an Investigational Device Exemption (IDE) prior to beginning the study. FDA then provides statistical, clinical, and engineering reviews of the preclinical data and investigational plan and weighs the potential benefits against the potential risks to determine if the participation of patients in the clinical study is justified.

DIAGNOSTIC DEVICE REGULATION

The FDA regulates diagnostic tests in several ways. One way has been through labeling; for microbial sensitivity diagnostics, this began in 1967 and has expanded to in vitro diagnostic (IVD) tests. As a result of the 1976 Medical Device amendments to the Food, Drug and Cosmetic Act, the same two mechanisms of pre-market regulation, the PreMarket Notification and the PreMarket Approval application, apply to diagnostic as well as therapeutic devices. In addition to the diagnostic device manufacturers which are regulated by the FDA, many in vitro diagnostic tests require laboratories which analyze the specimens and report the results. Laboratories are regulated in the United States by several congressional actions. In 1967, the Clinical Laboratory Improvement Act (CLIA) which regulated what are called high-complexity laboratories was enacted into law and in 1988 the CLIA Amendments expanded the scope from high-complexity laboratories to all laboratories, including physician’s offices. Many diagnostic tests may no pose any significant risk to the patient, in which

case an IDE would not be required; however, CDRH encourages companies to meet with the FDA before any clinical study is undertaken for regulatory consideration. For a discussion of some of the regulatory issues in genetic and genomic tests, see Ref. [8].

GLOBAL REGULATORY EFFORTS

Medical devices are regulated throughout the world. Governmental organizations that utilize statistical review in their evaluation of medical devices include the Medicines and Healthcare Products Regulatory Agency (MHRA) of the United Kingdom,^[9] Japan's Pharmaceuticals and Medical Devices Agency (PMDA),^[10] and Canada's Bureau of Medical Devices in Health Canada.^[11] Efforts are underway to harmonize medical device regulations among many countries throughout the world through Global Harmonization Task Force,^[12] an organization similar to the International Conference on Harmonization (ICH) for pharmaceutical products.

Design Issues in Non-Diagnostic Medical Device Studies

There are a number of important design issues that arise in the planning of medical device studies. A general FDA guidance document that describes many of these issues is "Statistical Guidance for Clinical Trials of Non-Diagnostic Medical Devices."^[13] For sample-size estimation, see the encyclopedia entry on "Sample Size Determination" because the sample size issues involved in medical device studies are similar to those in drug development.

Implants

While medical devices come in a mind-boggling array of shapes, sizes, and intended uses as well as attendant problems in evaluation, devices that are implanted provide special statistical challenges. For example, implants are usually meant to be in the body for a very long time, unlike a drug, which is usually out of the body shortly after the ingestion. Thus, how the implant interacts with the body, and the body with the implant over time, is important to evaluate. This poses some unique statistical challenges, especially regarding survival analysis,^[14] repeated measures (longitudinal data analysis), and missing data. In addition, implants, by definition, are *implanted*, usually in a surgical procedure; the safety and effectiveness of the implant may depend on the skill of the surgeon. Thus, the variability of patient outcome across study centers (or surgeons) may be a critical issue. There may even be (and often is) a *learning curve* where a surgeon becomes more skilled and results improve as a surgeon gains experience with the implant and implantation procedure. On the other hand, sometimes, devices can be predictable. Most medical

devices work through a localized, physical mechanism of action. Thus, bench testing and information from similar products may be useful in predicting how a new device will perform. Because medical devices do not fit nicely into a neat category where a single analytical approach is optimal, or even possible, the study design and analyses employed will vary greatly depending on the particular device and indication involved.

Sham Controls (The Placebo Effect)

One critical element in study design that represents a major departure from the usual pharmaceutical study lies in the choice of an appropriate control. The well-studied and highly successful placebo-control trial design is used less frequently in medical device evaluation. For many devices, there is no placebo arm possible, while for others, a placebo (or sham) would be unethical. For these reasons, approaches employing active or historical controls are much more common although this can introduce the knotty question of statistical bias. The placebo effect can be quite substantial in many studies where the primary outcome variable is pain or function. Kaptchuk considers whether there is, in some cases, an enhanced placebo effect for devices; if there were such an added effect for a new device, it would make its effectiveness more difficult to demonstrate.^[15]

While an active control may appear to be the more appropriate alternative, this type of control can bring major analytical challenges to the device arena. Consider, for example, an implanted nerve stimulator intended for weight reduction. In this case, the most appropriate control can be a drug intended for the same purpose. However, both the drug and the device probably have a placebo effect and the extent of the placebo effects may easily differ.^[16] This placebo-by-treatment interaction may be difficult or, at worst, impossible to estimate at the analysis stage.

Masking (Blinding)

Often in a medical device trial, it may not be possible to mask the health-care provider or the patient to the treatment because it may be quite apparent to all who has which device. It is nonetheless desirable that the third-party evaluator be masked if possible at all. Masking (or blinding) can avoid statistical bias.

Historical Controls

In some cases, a randomized trial with an active control may not even be practical or feasible. For example, in a rapidly advancing technology, it may be difficult and, sometimes, unethical to recruit patients for the control arm. In such cases, a single-arm study is often conducted, with the experimental device being compared to one or more historical controls from previous studies. A problem with this comparison is that the device effect is confounded by the

effect of the type of study as well as the device-by-study interactions. These confounding effects can result from differences between the studies in objectives, endpoints studied, protocol, patient population, investigational sites, physician training, and patient management. In fact, any variable confounds the comparison if it has an effect on the outcome of interest and the variable's distribution differs between the historical studies and the current study. Estimation of the treatment effect in a study with an historical control is considered in Zhang.^[17]

Sometimes, the historical control data are summarized by a single-target value. The comparison of the device to the target value not only can be confounded but also ignores the random variation inherent in the historical study used to create the target value. Bayesian hierarchical modeling could be used to address confounding and historical control random variation in the development of target values for medical device trials.^[18]

Noninferiority Trials

When establishing substantial equivalence, superiority is usually not the issue, and a superiority trial design usually does not make sense. For devices where there are alternative devices already available, knowing that a new device is no worse than a competitor may demonstrate that the new device is substantially equivalent to its comparator, or that it is safe and effective. For these reasons, the noninferiority trial design is an increasingly popular approach in evaluating medical devices. The fundamental principles of such noninferiority trials and statistical methodologies applied in the area of therapeutic devices are the same as in the area of drug development.^[19–24] However, some statistical issues and design questions have been encountered in this area more frequently than others.^[24]

In statistical terms, the null and the alternative hypotheses with respect to population mean in a noninferiority trial are specified as $H_0: \mu_c - \mu_e \geq \delta$ vs. $H_a: \mu_c - \mu_e < \delta$ where $\delta > 0$ is the prespecified noninferiority margin, μ_e and μ_c denote experimental and active control treatment means, respectively, and it is assumed that larger means are more desirable. While choosing the correct formulation of study hypothesis might not be an issue in most drug development applications, in some medical device submissions, the misleading hypotheses of $H_0: \mu_c - \mu_e = 0$ vs. $H_a: \mu_c - \mu_e \neq 0$ are still employed. As Blackwelder has pointed out,^[19] in determining whether a new device is as effective as a standard device, the test of the conventional null hypothesis of equal effects is inappropriate and leads to logical difficulties. In particular, failure to reject the alternative hypothesis does not establish noninferiority.^[25]

Choice of Active Control

An active control could be an FDA-approved device or an accepted standard of care. To demonstrate the effectiveness

of a new device, a noninferiority study should have the ability to distinguish effective from ineffective products. One crucial requirement is the implication of the active control treatment effect; that is, the active control selected should be known to be effective in the planned study because equivalence/noninferiority to an ineffective comparator is meaningless.

Choice of Noninferiority Margin

Another crucial consideration concerns the choice of an acceptable noninferiority margin, δ . This quantity should be sufficiently small so that from a clinical point of view, the new device can be considered to be as good as the control (and, therefore, effective) as long as the new device is no more than δ worse than the active control. In particular, the choice of δ should not lead to a situation where the new device is only slightly better or even worse than no treatment.

When planning a study and sizing it, the specification of the population parameters, μ_e and μ_c , has to be clinically meaningful and reasonable. The treatment effects for the new and active control are frequently set at the same level, meaning the new device is expected to perform as well as the control although somewhat lesser performance may be tolerable. However, the possibility that the active control is more effective than the new device might be more realistic in some noninferiority medical device trials. For example, in a comparison of invasive and noninvasive devices, if it is known that the noninvasive device has somewhat inferior effectiveness performance compared to the invasive active control but has other significant benefits, it may be more realistic to allow that the active control is slightly better.

As a matter of fact, a superiority study and a noninferiority study can be practically planned at the same time, but it is essential that the planning be done in advance of carrying out the study.^[23]

Surrogates

Surrogates can play an extremely important role in the evaluation of medical device effectiveness. In the case of implants, even a premarket study of, say, 3 years may not predict the long-term behavior of the implant. Unlike drugs, where most of the drug is cleared from the system in a moderate amount of time after use is discontinued, an implant is there until it is surgically removed (if that is even possible). Thus, the long-term effects of the device are of interest. The ability of a surrogate to provide insight as the performance of the primary endpoint can streamline the introduction of the medical device into the marketplace. However, it is not sufficient to validate any surrogate merely to show strong correlation between it and the primary endpoint; general conditions for valid surrogates are put forth by Prentice.^[26] DeMets^[27] considers the difficult issue of surrogate endpoints in medical device trials.

Monitoring

There are important statistical issues that arise in the monitoring of medical device studies. This includes patient accountability (missing data), modifications in the protocol or in the device, sample-size re-estimation, and sequential monitoring. Another issue that arises in device trials is called crossover, not the statistical design but the notion of transferring patients, usually for ethical reasons, from one therapy to another during the study. For implants, this can create the inability to do long-term follow-up on both arms.

Analysis

Many of the same issues arise in the analysis of medical device studies as are encountered in the analysis of pharmaceutical trials. A few of the notable statistical issues that may be somewhat different for device studies follow.

Center-by-Treatment Interaction

In device trials, center-to-center variation in the device effect can be large. The main reason is sometimes large variation between centers in physician experience and training in using or implanting the device. Other reasons include variability between centers in patient population, patient management, and reporting practices. When center-by-device interactions are large or are qualitative (i.e., the device effect changes sign depending on the center), then a scientifically credible explanation is required at the minimum. Sometimes, close scrutiny of the centers can reveal explanations for the interactions.

Repeated Measurements

Repeated measurements are generated when a study subject is observed on several successive follow-up times, occasions, or experimental conditions. The use of repeated measurements in medical device studies has become increasingly popular recently. There are generally two types of frequently used repeated measurement design in therapeutic device trials: single-arm studies (studies without a concurrent control group) and two-arm, randomized, possibly masked, controlled trials. In a single-arm study, the hypothesis of interest is usually to compare pre-treatment and post-treatment effects or to evaluate the effect of device over follow-up times. In a two-arm study, there are generally three types of hypothesis of interest: treatment-by-time interaction, treatment effect, and time trend. The equivalence of diagnostic assay methods is often evaluated with matched-paired repeated measurements through regression model, repeatability, and reproducibility studies. There are mixed types of data seen in medical device clinical studies including continuous, binary, and ordinal data. Appropriate statistical analysis incorporating

correlation structure among repeated measures within a subject and important covariates is needed.^[28–31]

Subgroup Analysis

Planned subgroup analysis can test for significant effects within subgroups. For example, for spinal fusion devices, the device effect could be significant for obtaining fusion at one level of the spine, but not for obtaining fusion at two contiguous levels. When the device effect is only significant for some of the subgroups, then the inferences should be adjusted for multiple comparisons.^[32]

Causal Inference

In many medical device studies, the actual device effects may be distorted because of statistical biases introduced by the design and the conduct of the study. For example, bias is introduced by lack of masking of treatments to patients and investigators, nonrandomized comparisons with historical controls, noncompliance, missing data, censoring of quality-of-life variables due to death, etc. When a study has a known or suspected bias, causal inference theory can be used to tease out the actual or causal treatment effect from the bias. As a result, the theory can provide a framework for investigating biases inherent to studies. For example, Frangakis and Rubin^[33] employ the causal inference method of principle stratification to obtain estimates of causal effects in studies complicated by post-treatment variables such as noncompliance. Other causal inference methods include propensity scores and sensitivity analysis as discussed below. Other causal inference topics are counterfactuals, randomization theory, structural equation models, path analysis, and directed acyclic graphs. The causal inference literature is growing and may prove to be very helpful in evaluating medical devices.^[34]

Propensity Scores

Propensity scores are used to adjust nonrandomized comparisons for covariates. For medical devices, they can be useful when an experimental device is compared with a historical control using patient-level information in the two data sets. In this context, the propensity score $e(X)$ for a subject with a vector X of observed covariates is the conditional probability of receiving treatment ($Z = 1$) rather than control ($Z = 0$) given X ; i.e., $e(X) = \Pr(Z = 1 | X)$.^[35–37] The propensity score $e(X)$ is a balancing score in the sense that it is a function of the observed covariates X such that the conditional distribution of X given $e(X)$ is the same for subjects in the treatment group and subjects in the control group (1). If treatment assignment is strongly ignorable, that is, the treatment assignment Z and the potential outcome Y are conditionally independent given the observed covariates, X , i.e., $\Pr(Z | X, Y) = \Pr(Z | X)$, and if $0 < \Pr(e(X)) < 1$, for all X , then the observed treatment effect at

each value of the propensity score is an unbiased estimate of the true treatment effect at that propensity score.^[35] Propensity score matching, stratification, weighting, covariate adjustment, and some combination of these strategies can then be used to produce an unbiased estimate of the average treatment effect (Ref. [35–40] and references therein). In application, the propensity score is estimated by modeling the probability of treatment group membership as a function of the observed baseline covariates via, for example, a multiple logistic regression. The assumption of strongly ignorable treatment assignment requires that all covariates relevant to both treatment assignment and potential outcomes are measured (i.e., there is no hidden bias).

As pointed out by Rubin,^[37] as a balancing score, the propensity score is a one-dimensional summary of the observed covariates such that when the propensity scores are balanced across two treatment groups, the distribution of all the covariates are balanced in expectation across the two groups. Therefore, evaluating treatment group overlap in terms of the distributions of propensity scores provides a straightforward assessment of whether the two treatment groups are sufficiently similar with respect to baseline covariates to allow a sensible treatment comparison. When sufficient overlap is present, the propensity score analysis can provide a straightforward treatment comparison that reflects adjustment for differences in all observed baseline covariates. Otherwise, as indicated by Rubin,^[37] either the propensity score prediction model would need to be reformulated or it would have to be concluded that the covariate distributions did not overlap sufficiently to allow propensity score analysis to adjust for these covariates. Therefore, in a regulatory environment, it is crucial to start with comparable patient populations, since propensity score analysis does not work well (in fact, no statistical method works well) when there is serious imbalance in baseline covariates between the two treatment groups.^[41,42]

Like other covariate adjustment methods, propensity score methods can only adjust for observed covariates and not for unobserved ones. This is always a limitation of non-randomized studies compared with randomized trials where randomization tends to balance both observed and unobserved covariates. Therefore, some sensitivity analysis for hidden bias is often desirable in a medical product regulatory submission based on a non-randomized study. It should also be noted that propensity score methods may not eliminate all the bias resulting from imbalance in the observed covariates, due to the limitation of propensity score modeling, which typically uses a linear combination of covariates.^[37] Braitman and Rosenbaum^[43] state that the propensity score methods work better under three conditions: first, when clinical outcome event is rare, second, when there are a large number of patients in each treatment group, and third, when there are many covariates measured.

Rubin^[44] emphasizes the importance of designing of observational studies prospectively, and advocates

that observational studies can and should be designed to approximate a randomized experiment as closely as possible before any access to any outcome data, thereby assuring the objectivity of the design. Particularly in a regulatory environment, the prospective design of a non-randomized confirmatory study with propensity score analysis specified as primary analysis is essential, in order to provide valid and convincing evidence of safety and effectiveness of a medical product.^[41,42]

Sensitivity Analysis

Sensitivity analyses quantify how sensitive inferences are to statistical biases that might be present in studies. For medical device studies under regulatory review, such analyses can be used to demonstrate that inferences are robust to potential sources of bias such as missing data, placebo-by-treatment interactions, and unmeasured variables that confound comparisons of devices with historical controls. For example, a significant device effect may still be regarded as significant in the presence of an unmeasured confounder if it is large enough. However, the device effect has to be larger than if that bias did not exist. Thus, there is a trade-off between the clinical burden of a well-designed and well-conducted study (e.g., a randomized controlled trial with no missing data) and the statistical burden of less than ideal studies (e.g., a one-armed study comparing an experimental device to a historical control) that introduce statistical bias. An example of a missing data sensitivity analysis for a medical device trial was presented at a recent Orthopedic and Rehabilitation Devices Advisory Panel; the interested reader is referred to the Summary of Safety and Effectiveness for this spinal fixation product.^[45] Sensitivity analysis methodology for an unmeasured confounding variable is given in Rosenbaum^[46] and in Lin et al.^[47]

DIAGNOSTIC DEVICES

Diagnostic Design Issues

Diagnostic devices differ from therapeutic devices in a fundamental way. Rather than treating a patient with a specific condition, diagnostic devices are intended to determine whether the patient has the specific condition. Thus, diagnostic studies pose different statistical challenges in terms of both the design and the analysis. The design of most of these studies involves using the diagnostic device to test patients with and without the condition of interest and determining how often the diagnostic test is correct. While this design may seem simple in concept, it can be very difficult to actually carry out. One major problem is in identifying the patients who truly have the condition. Often, this is done with another diagnostic test. When that test is extremely accurate so that a *truth standard* (sometimes called a “gold standard”) exists, then defining the

accuracy of the new test is relatively straightforward. When the comparison test is less than ideal, the study becomes a comparison of two tests, where, even when they agree, neither may be correct.^[48] These issues are approached from a regulatory perspective with the FDA Guidance document “Statistical Guidance on Reporting the Results from Studies Evaluating Diagnostic Tests.”^[49]

The Randomized Clinical Trial, a design that is so often relied upon in therapeutic trials, is of limited use in many diagnostic evaluations. It is generally much more efficient to use each patient as his/her own control in the diagnostic setting. It is often simple to subject each patient to both diagnostic procedures (although whether the order of the tests is important may depend on the situation); further, if the two tests are correlated, this design can be extremely efficient. However, bias can become an overwhelming issue. In particular, the performance of a diagnostic test can be greatly affected by the selection of the patients. The order in which the two tests are conducted can sometimes also produce bias. Verification bias, the bias introduced when the gold standard is missing for some patients, is also present in many diagnostic studies. For an example of verification bias and a proposed remedy, see Kondratovich.^[50] Thus there has to be exceptional vigilance to ensure that all the different sorts of statistical biases do not threaten the scientific validity of the clinical diagnostic study. Begg^[51] and Pepe^[52] survey many of the biases that can plague diagnostic studies.

Diagnostic test results have little clinical value if they do not confer any additional diagnostic information beyond information already available from standard assessments. For example, a prostate specific antigen (PSA) test should add diagnostic value over the digital rectal exam in detecting prostate cancer. As another example, bone density, as measured by a bone densitometer, should add value as a risk factor for bone fracture after considering a patient's age.

In terms of reporting the performance of a new diagnostic medical device, sensitivity and specificity are most helpful when using a truth standard (“gold standard”). Unfortunately, there is often no truth standard because even if there is some standard for disease classification, it is usually not perfect. For example, a standard may be accurate if the disease is detected, but less than perfect if the disease is not detected. Without a truth standard, it is impossible to report sensitivity and specificity in a direct manner. One approach that some have attempted is to compare the new device to another test (not a truth standard) and then subject the cases that are discrepant to another perfect or imperfect test. Such a practice inevitably results in biased estimates of sensitivity and specificity that may be very misleading.^[53] Recent research into treating the prevalence as an unknown parameter that can be estimated using the expectation-maximization (E-M) algorithm may hold some promise.^[54] Another approach called *method comparison*, which is discussed in the “Measurement

Method Comparison for Diagnostic Tests,” can be used to compare the new test with another diagnostic test. There are a number of interesting statistical problems associated with the demonstration of agreement.^[55] Regardless of the approach, however, without a truth standard, such a comparative agreement approach can only answer questions about equivalence, but not superiority.

Analysis Issues for Diagnostic Devices

The statistical analysis for diagnostic devices is generally quite different from that for therapeutic agents. When truth is known, statistical inference using confidence intervals rather than hypothesis testing is often much more useful in reporting the performance of a dichotomous test. When the threshold or cutoff is on a continuous or ordinal scale, it is particularly helpful to use receiver-operating characteristic (ROC) methodology.^[56] For studies with important covariates, logistic regression is a useful tool. For studies that rely on agreement, kappa and percent agreement positive and negative are helpful although the null value of kappa equal to zero is not of interest. In some instances, especially for diagnostic imaging, the skill of the image reader can be quite important. In such cases, it may be helpful to use variance components and bootstrapping to study the variability due to readers as well as due to cases and to design the study accordingly.^[57] For comparative studies, sample size can be difficult to determine because the correlation between two diagnostic tests can be unknown *a priori*, suggesting that sample size should be determined adaptively.^[58] An overview of statistical analysis for medical imaging is given in Chow and Shao.^[59]

Measurement Method Comparison for Diagnostic Tests

The purpose of a diagnostic device study with quantitative measurements is usually to assess whether the new device is comparable to an established one. Here comparable means equivalent, which can be defined in different ways including *average equivalence*, *population equivalence*, or *individual equivalence*.^[60–63] Evaluating average equivalence could be done using regression analysis and assessing the closeness of the slope to 1 and the intercept to 0. Key considerations in this type of analysis would include:

- Criteria for claiming equivalence
- Errors in measuring both X and Y
- Variance assumptions.

The statistical model could be specified as follows: Y indicates the measurement with the new device, with mean y and random error ε ; X represents the measurement using the established device, with mean x and random error η , with random errors ε and η independent. The unobserved

mean values x and y have a linear relationship with intercept β_0 and slope β_1 :

$$Y = y + \varepsilon, \quad X = x + \eta, \quad y = \beta_0 + \beta_1 x$$

For purposes of illustration, consider the criteria for regression slope equivalence as closeness of slope to 1 and closeness of intercept to 0. In assessing slope, a power approach has often been used, with the statistical null hypothesis of slope equal to 1 and the alternative hypothesis of slope not equal 1:

$$H'_0 : \beta_1 = 1$$

$$H'_a : \beta_1 \neq 1$$

Regression equivalence for the slope could be claimed if the null hypothesis were not rejected or, equivalently, if a 95% confidence interval on slope includes 1, provided there is sufficient power to detect an important difference. Usually, the sample size is calculated at a nominal α level of 0.05% and 80% statistical power to detect a slope that differs from the null slope of 1 by a clinically meaningful value of, say, 0.1. The logic underlying the power approach is that if the slope had actually been 1.1 (or larger), the probability is at least 80% that the null hypothesis of slope equal to 1 would have been rejected at level α . Thus, if the null hypothesis is not rejected, it is concluded that slope was not as large as 1.1; that is, the equivalence is achieved. However, as pointed out by Schuirmann,^[63] this test leads to logical difficulties. For example, insufficient evidence to reject the null hypothesis of equality does not imply sufficient evidence to accept it. If the slope is actually clinically different from 1, but the desired result is the failure to find it,^[1] that result is easier to obtain with a small study than with a large one. There is actually a penalty for conducting an efficient trial with a narrow confidence interval.

By contrast, an interval hypothesis procedure, commonly used in pharmaceutical bioequivalence studies, does not have these disadvantages. Consider the hypotheses

$$H_0 : \beta_1 \leq 1 - \delta \text{ or } \beta_1 \geq 1 + \delta$$

$$H_a : 1 - \delta < \beta_1 < 1 + \delta$$

where δ is a clinically meaningful equivalence margin. This procedure is a familiar one in assessing equivalence of average bioavailability/bioequivalence.^[64,65] Regression equivalence of the slope could be claimed if the null hypothesis is rejected or, equivalently, if a two-sided 90% confidence interval on slope lies entirely within the equivalence interval $(1 - \delta, 1 + \delta)$. Average equivalence would also require inference about the intercept as well; and individual equivalence additionally requires some assurance in

this slope-intercept regression approach that the variance about the fitted line is small.

In terms of analysis, errors in measurements and underlying variance assumptions are critical issues. Because the measurements obtained from both the new and the established devices are subject to random measurement error, using a simple model that ignores the errors in measurements from *both* devices will lead to bias in parameter estimates and inferences. Hence, more complex methodologies, such as measurement error models, e.g., Deming regression^[66] or Passing-Bablok regression^[67] should be used. Assumptions about variance are also critical in these assessments. When, as is often the case, the variance of these measurements quite commonly increases as the true reference value increases, this heteroscedasticity in variance must be taken into account, otherwise the subsequent test for measurement method equivalence will be invalid.

INDIVIDUAL EQUIVALENCE

To evaluate individual equivalence, one could, for example, characterize the distribution of the differences between paired measurements, Y and X , from the two devices across the measurement range, and evaluate whether $P(|Y - X| < d)$ is close to 1 for a given $d > 0$. A graphical presentation of individual agreement is the Bland-Altman scatter plot of the differences $(Y - X)$ against the mean of the measurements $((X + Y)/2)$ to enable assessment of the scatter for uniformity and symmetry about zero.^[68] The 95% limits of agreement, the average difference plus or minus two standard deviations, is also useful to compare against d .^[69] Another measure of individual agreement is the individual equivalence criterion (IEC)^[70] which compares the variability between modalities to the variability within a modality, which for 510(k)s is naturally the predicate device. Coefficients of accuracy and agreement have also been developed.^[71]

Diagnostic Imaging

Imaging systems are medical devices which are becoming an increasingly important in diagnostic medicine. Examples of diagnostic imaging include digital mammography, ultrasound, chest x-ray, computed tomography (CT) scans, and magnetic resonance imaging (MRI). Diagnostic imaging usually involves interpretation of the image by a reader, e.g., a radiologist reading a mammogram for suspicious lesions. Computer assisted diagnostic devices (CAD) provide information to aid the reader's interpretation of the image. CADs have been developed for breast, lung, and colon imaging to detect abnormalities, such as malignant lesions. The evaluation of imaging systems and CADs can pose unique design and analysis challenges, including estimating intra- and inter-reader variability.^[72,73]

Monitoring Devices

Many diagnostic devices monitor patients for conditions of interest. Examples include bone densitometers, fetal heart rate monitors, glucose monitors, and pulse oximeters. Sample size determination for studies of monitoring devices that involve repeated measurements is discussed in Pennello.^[74]

Analytical Studies

For *in vitro* diagnostic tests, analytical performance should be characterized. Analytical performance refers to accuracy of the test in detecting an analyte or quantifying its concentration. Analytical performance also can include bias relative a predicate or reference test, test precision (repeatability), analytical specificity, and when appropriate limits of detection or measurement. Determining the limit of detection is discussed in Linnet and Kondratovich.^[75]

Biomarkers, Diagnostic Tests, and Microarrays

Biomarkers play an important role in many clinical studies, whether they involve other medical devices or not. A large number of biomarkers are obtained from medical devices, such as blood pressure, medical imaging, and genetic and genomic tests including microarrays. A question in some cases is whether the biomarker can serve as a surrogate or a partial predictor of disease or of response to treatment. Biomarkers can help to predict outcome in the presence of the standard treatment or no treatment (prognostic biomarker) or to predict differential efficacy or safety associated with a particular treatment (predictive biomarker).^[76] Biomarkers may prove to be indispensable in selecting the right therapies for the right patients, in short, in personalizing medicine. Technologies such as microarrays, which measure gene expression for a large number of genetic segments, are fueling some of the excitement associated with the discovery of new biomarkers. For example, MammaPrint®, by Agendia, is an FDA-approved microarray-based prognostic biomarker for risk of distant metastasis of breast cancer.^[77] Microarray-based classifiers pose interesting challenges in development, validation, and FDA regulation^[78,79] and are a subset of In Vitro Multivariate Index Assays, the subject of FDA draft guidance.^[80,81]

Bayesian Approach in Evaluating Medical Devices

Bayesian statistics is playing an increasing role in pre-market medical device studies. In several well-planned successful submissions to the FDA's CDRH, a Bayesian approach has provided the primary basis for the statistical analysis. Bayesian statistical analyses take advantage of prior information on safety and effectiveness parameters by formally combining this information with clinical data via Bayes Theorem.

At the FDA's CDRH, the ability to take advantage of prior information has very attractive regulatory implications. In device development, improvements tend to be incremental; thus, there is usually an older version of the device, often with associated clinical testing. These clinical data are often relevant. For example, implantable and therapeutic devices tend to have a physical mechanism of action. Thus, rather than dealing with potential major systemic reactions, small changes in such a device tend to result in only a small change in a localized effect. Using Bayesian methods to take advantage of prior information often leads to estimates of effectiveness and safety parameters that are more precise than if the prior information were ignored. Therefore, by utilizing prior information, CDRH can, in principle, reach the same decision on a device with smaller and perhaps shorter trials.

When prior information is not available, the Bayesian approach can still be helpful. For instance, the Bayesian approach can be more flexible than the frequentist approach with regard to interim looks,^[82] missing data,^[83] multiplicity,^[82] and adaptive modifications of trials such as changes to the sample size and dropping of a treatment arm.^[84] In addition, Bayesian inferences provide exact posterior distributions of parameters, while many frequentist methods appeal to asymptotic theory, which may not be appropriate for small-sized studies or for rare events.

Practical applications of Bayesian analyses are discussed in the excellent texts by Spiegelhalter et al. and others^[85–88] A tutorial of Bayesian methods for medical device development is given in Berry.^[89] Pennello and Thompson^[90] discuss a variety of issues concerning Bayesian medical device trials under regulatory review.

Bayesian Statistics in Brief

Most of the familiar techniques in statistics are referred to as frequentist. The frequentist approach considers parameters as fixed unknown quantities. In contrast, the Bayesian approach considers parameters to be random quantities with a probability distribution. In the Bayesian approach, probabilities are assigned to parameter values prior to the data being observed. These probabilities are called the prior distribution. When study data are later observed, the prior distribution is mathematically updated to the posterior distribution, according to Bayes Theorem. The posterior distribution is then used to compute posterior probabilities of important hypotheses. If the posterior probability of a hypothesis is large enough, then the hypothesis is accepted. This approach provides a scientifically valid way of combining previous information with current data.^[91]

FDA's CDRH has released a draft guidance document on the use of Bayesian statistics in medical device clinical trials.^[92]

Valid Prior Information

Sources and validation of prior information for medical devices under regulatory review are discussed in Irony and Pennello^[93] and Pennello and Thompson.^[90] The prior information is usually based on data from other studies. These prior studies should be similar to the current study in protocol (endpoints, target population, etc.) and timeframe, e.g., to ensure the practice of medicine in the studies is similar. Covariates, such as demographics and prognostic variables, can be extremely helpful in calibrating the previous studies to the current study. Covariate adjustment is often necessary to ensure that the prior studies are exchangeable with the current study, an assumption commonly invoked in Bayesian hierarchical models for combining the studies. The previous studies should also be representative of the possible studies that could have been selected.

Bayesian Sample Size

The Bayesian approach does not require the sample size to be fixed at the study outset because inferences are based not on the sample space, as in the frequentist approach, but on the parameter space. That is, the posterior distribution represents probabilities for parameters, not data. In practice, however, a minimum sample size may be required to evaluate safety parameters (which are often rare adverse events), to verify model assumptions or to ensure that the prior does not overwhelm the clinical data. A maximum sample size may be needed for economical or ethical reasons or for planning the logistics of the trial. Bayesian approaches to sample-size determination include those based on power to make decisions^[94,95] interval length and coverage probability,^[96–98] and decision theory.^[99] Because the sample size is not fixed, it can, in principle, be revised at any point in the study by considering the current posterior distribution instead of the prior distribution.

Bayesian Interim Looks

Bayesian interim analyses do not depend on the stopping rule, provided it is non-informative. This is the Stopping Rule Principle, which is a consequence of the Likelihood Principle,^[100] adhered to in Bayesian analyses. Consequently, Bayesian interim analyses do not depend on the number of interim looks. Nevertheless, in the regulatory setting, the Type 1 error that a medical device is approved when it is not safe and effective is a major concern, and the Type 1 error rate is inflated if interim analyses are made. Therefore, the FDA's CDRH usually recommends that the sponsor computes the Type 1 error rate for the design they are considering.

One Bayesian interim monitoring strategy stops patient accrual when the posterior probability of the primary hypothesis of interest exceeds a pre-specified threshold, e.g., 0.975. However, if outcomes are not yet available for

patients just accrued to the trial, a better strategy is to monitor the predictive probability that when these outcomes are observed, the posterior probability threshold will be met. One could also monitor the predictive probability of success at the end of the study were it not stopped. Stopping criteria can also be based on formal decision analysis.^[101] For more information on Bayesian interim analysis for medical devices.^[90,102]

Bayesian Adaptive Design

Adaptive designs use accumulating data to decide on how to modify certain aspects of a trial according to a pre-specified plan. Because of the Likelihood principle, a Bayesian approach can offer flexibility in the design and analysis of adaptive trials. Some examples of adaptive designs for medical device trials are sample size modification, adaptive randomization,^[103] and the dropping or adding of an arm because of safety concerns or lack of enrollment. Another example is a hybrid trial, during which an inactive control, e.g., no device, is replaced with an active control, e.g., a recently approved new device, when investigational sites begin to use the active control in their practice, in anticipation that once the investigational sites begin using the recently approved device, randomization to the no device control arm would become unethical. In turn, the primary hypothesis changes from one of superiority to the inactive control to one of non-inferiority with the active control. A specific instance is hybrid trials for embolic protection devices, which collect potentially harmful emboli caused by placement of coronary stents.^[104]

Historical Controls as Prior Information

A frequent application of Bayesian statistics uses historical control data as prior information for the control arm in a randomized controlled study.^[105] This prior information translates to additional sample size for the randomized control;^[106] thus, fewer patients need to be randomized to it. Hierarchical modeling (see the section “Bayesian Hierarchical Modeling”) of the studies can be used to account for between-study and within-study variation of the controls. For a single-armed study without a randomized control, historical controls can still be used as prior information to derive a synthetic control arm.^[107]

Bayesian Noninferiority Testing

Some commonly used prior distributions are not appropriate for noninferiority trials. “Non-informative” priors center the experimental device effect at zero, implying a prior probability of noninferiority that is greater than 50%. If it were really the case that no prior information is available, then the prior probability should be exactly 50%. Similarly, hierarchical models (see the section “Bayesian Hierarchical Modeling”) on the experimental device and

control arms center the device effect at zero. Additionally, they use data on one arm as prior information for the other, which pulls the device effect toward zero, i.e., toward the region of noninferiority. This prior can be difficult to justify because it assumes what is sought to be proved by the study, namely, that the experimental device is similar (non-inferior) to the control.

Bayesian Hierarchical Modeling

Bayesian hierarchical modeling^[108] is a flexible approach for combining previous device studies with a current study. These models separate variation between studies from variation within studies by assuming that study-specific parameters are random. These random effects enable the current study to borrow strength from the previous studies, i.e., use them as prior information. This usually results in more precise estimates of the current study parameters; however, that is not always the case.^[109] Hierarchical models are flexible in that the current study borrows less strength from the previous studies as the variation between studies increases. Thus, hierarchical models protect against overreliance on bad prior information, which is an attractive property, especially in the regulatory setting.

Hierarchical models can also be used to combine data across centers in a multicenter device trial. Between-center variability, which can be large in device trials, is accounted for by assuming that center-specific device effects are random.

Hierarchical models can also be used to adjust subgroup analyses for multiplicity effects.^[110] Briefly, subgroup effects that are considered related are assumed random. Thus, the estimate of each subgroup effect borrows strength from related subgroups. A subgroup that has a large observed effect will have that effect adjusted downward if the related subgroups have mostly small observed effects.

Bayesian Calculations

Bayesian calculations require integration, usually in high dimensions. For example, the posterior probability of a hypothesis is expressed as an integral involving the posterior distribution. Until recently, the high dimensionality of these integrals made Bayesian calculations prohibitive. Advances in Markov Chain Monte Carlo (MCMC) sampling methods^[111] and computing speed have enabled calculation of these integrals and are the main reasons that the field of Bayesian statistics has become popular in recent years.

A popular MCMC method is Gibbs sampling. Gibbs sampling avoids the problem of sampling from the posterior distribution, which is often infeasible. The Gibbs sampling method creates a Markov Chain by sampling sequentially from the posterior distribution for each parameter conditional on the last sampled values of the other parameters and the data. These distributions are called full conditional

distributions. Often, the full conditionals can be written in closed form, making sampling from them straightforward. Under mild regularity conditions, the sampling distribution converges to the posterior distribution. Once the sampling distribution has converged, subsequent samples can be used to compute desired Bayesian integrals. Because the samples form a Markov Chain, they are dependent samples. Therefore, enough samples need to be taken such that the support of the posterior distribution has been completely explored. A Bayesian statistics program that uses Gibbs sampling is Bayesian inference Using Gibbs Sampling (BUGS).^[112]

STATISTICAL ISSUES IN THE POSTMARKET

Medical devices are also studied in the postmarket phase; the longer-term safety of new medical devices is often monitored after they have been approved for marketing. The ability to decide on the seriousness of a medical device adverse event depends on exposure. Information concerning the number of devices in the hands of the intended users is often not well known; hence, exposure may be most difficult to estimate. In addition, there is a well-recognized, serious underreporting of adverse events that may be associated with devices; this can create a severe bias. Furthermore, even if there is an adverse event reported in conjunction with the use of a medical device, it may be difficult to ascertain whether the device caused the adverse event. Different statistical methodologies have been proposed to address these difficult problems in postmarket surveillance of both medical devices^[113,114] and drugs,^[115] e.g., a Bayesian approach using a gamma-Poisson model for the latter.

CONCLUSION

The future of medical devices poses no end of exciting and challenging issues for the development of new statistical methodology. Indeed, a special issue in *J Biopharmaceutical Statistics* was recently devoted to medical devices.^[116] It is predicted that the pace of medical device revolution will continue to accelerate. The speed and the variety of the new technology will encourage new statistical methods to meet these challenges. The globalization of the medical device industry will pose challenges to the regulators as efforts are made to harmonize requirements for demonstrating safety and effectiveness.

Abstract

In this entry, the focus is primarily on the meta-analysis of randomized therapeutic trials in which aggregated, or summary, estimates of treatment effect are combined.

INTRODUCTION

How can a large amount of independent quantitative information on the same question come together in a coherent and meaningful manner? Many researchers have relied on meta-analysis to achieve such synthesis of evidence. Traditional journal review articles and textbook chapters, upon which most clinicians have traditionally relied for therapeutic guidance, generally tend to make selective and subjective appraisals of the evidence and usually do not provide a quantitative synthesis of the data.^[1] Although it can be applied to data of any sort, meta-analysis has been commonly used to combine results from different studies to draw conclusions about treatments.

“Meta-analysis” may be defined as the statistical analysis of data from multiple studies. A meta-analysis typically identifies data systematically, summarizes results, and evaluates quantitatively sources of heterogeneity and bias. A systematic literature review encompasses an explicit and detailed description of how a review was conducted. Some have characterized meta-analysis broadly to include a literature systematic literature review, as well as the statistical analysis of data. In this sense, meta-analysis has been also referred to as a quantitative systematic review or an overview.

The advent of the meta-analytic research method in the biopharmaceutical sciences has paralleled the explosion in the number of randomized trials being conducted and the increasing need to provide an unbiased quantitative synthesis in the era of evidence-based medicine and comparative effectiveness. Meta-analysis thus far has used mostly data from completed trials, but there is an increasing momentum for using the same principles of data synthesis in the prospective design of sets of clinical trials addressing a similar question.^[2,3] Meta-analysis has also been applied to

epidemiological studies to derive better risk estimates and to evaluations of diagnostic tests to obtain more reliable estimates of test performance. The basic statistical principles of meta-analysis can be expanded to apply to diverse types of data. In this chapter, however, we focus primarily on the meta-analysis of randomized therapeutic trials in which aggregated, or summary, estimates of treatment effect are combined.

We provide a review on the application of meta-analysis as a reference to aid pharmaceutical scientists, regulatory reviewers, and biostatisticians who are engaged in pharmaceutical research and development. The section “Benefits and Limitations” highlights the benefits and limitations of meta-analysis. “Statistical Analysis for Discrete Data” discusses common statistical methods for pooling discrete data from two-by-two contingency tables. “Statistical Analysis for Continuous Data” focuses on a method of pooling continuous data from multiple studies. The section “Basic Steps in Performing and Evaluating a Meta-Analysis” covers the basic steps to perform and evaluate a meta-analysis of randomized therapeutic trials. “Applications” illustrates several applications on how meta-analysis has helped to determine optimal therapeutic use and to enhance the understanding of the efficacy, safety, and cost-effectiveness of different pharmaceuticals. Finally, the section “Some Key Developments” highlights some of the major key methodological developments and advancements.

BENEFITS AND LIMITATIONS

Benefits

Meta-analysis offers several benefits. It may be used to address uncertainty and heterogeneity when results of

studies disagree, to increase statistical power for primary outcomes and subgroups, to improve estimates of treatment effect, and to lead to new knowledge and formulation of new questions.^[4] It is also a powerful tool for exploring sources of heterogeneity and bias in clinical research. The rapidly increasing volume of research, often with discrepant findings, has led to an increased need for meta-analysis. We identified 225 published meta-analyses of randomized controlled trials in 1993, compared with 7 in 1980. At least 500 meta-analyses of randomized trials were published in 1996 and 1997 alone. Several thousands of meta-analyses have been published to date, and thousands more are on the way.

Pooling results from studies with inadequate sample sizes may lead to a more precise and statistically significant estimate of a treatment effect. Applying regression methods to combined (pooled) results from studies may help to explain heterogeneity of treatment effects and differences across studies; as such, enhanced understanding may be gained and research hypotheses may be generated and subsequently evaluated. A comprehensive, well-done meta-analysis may help the researcher to know the strengths and weaknesses of the studies and therefore may aid in the design and analysis of future studies, which may bring about improvements in the quality of research. Finally, when performed prospectively, a meta-analysis may serve as a tool for planning the collection and analysis of large-scale evidence.

Limitations

Several criticisms have been leveled at meta-analysis.^[5,6] The major limitation of retrospective meta-analysis is that it is based only on what studies are available. An offshoot of this is the “apples and oranges” phenomenon pertaining to the external validity (generalizability) of the process: Combining different studies may lead to uncertainty as to which study or to what specific combination of studies and populations the results apply to. Furthermore, the studies available for pooling may vary in design, quality, outcome measures, or populations studied, calling into question whether it is logical and useful to combine their results. To address this issue, the researcher should prepare a protocol that includes well-defined criteria and objectives for including the studies in a meta-analysis as well as plans for subgroup analyses and regression analyses that may examine differences (heterogeneity) among studies. Another way to address this is to adhere to guidelines, whenever feasible, on the quality of reporting of meta-analyses.^[7]

Publication bias is a second limitation of using only available studies. Publication bias is induced when the decision to publish is influenced by whether the study result of an experimental treatment is “positive” (i.e., favorable and statistically significant) or “negative” (i.e., statistically unfavorable or not statistically significant). Theoretical and empirical evidence suggests that, if the treatment effects

of the studies included in the meta-analysis are found to be related to the sample size or the variance of the treatment effects, this association in some occasions may suggest publication bias,^[8] as small negative studies are more likely to be unpublished than large ones.

On the other hand, it can be argued that unpublished data have not been evaluated by peer review and therefore may be of dubious quality and should not be trusted. Although a source of concern, if there are only a few unpublished studies and each has a small sample size, their omission may be less likely to cause a substantial problem because they may then have minimal impact on the overall result. Nevertheless, there is evidence that even large efficacy trials may suffer from “publication lag”,^[9] a term coined to reflect the situation when negative efficacy trials appear in the literature with a time lag compared with their positive counterparts which are completed, submitted, and published more promptly. This may result in larger treatment effects in meta-analyses of the early evidence.

Several tests have been suggested in the literature to detect the possibility of publication bias, and some of them such as the “funnel plot” in which a measure of precision (e.g., sample size or the reciprocal of the variance) is plotted against the treatment effect are popular and commonly applied.^[8] Non-parametric^[10] and parametric methods^[11] to formally test for such funnel asymmetry have become accepted. When selection bias is present, the plot becomes asymmetrical, and the overall effect of the meta-analysis is biased. Empirical research, though, indicates that the shape of a funnel plot may be largely determined by the arbitrary choice of the method to construct the plot (i.e., by the definition of precision and the effect measure).^[12] Asymmetry in a funnel plot may also stem from the heterogeneity of treatment effect across studies as well as from chance and subjectivity.^[13] Overall, visual assessment of funnel plot asymmetry is an unreliable method, and even formal statistical methods for assessing asymmetry can only tell at best whether small studies tend to have different results from large studies (small-study bias), which may have nothing to do with publication bias.^[14]

In mitigating publication bias, research registries^[15,16] and other reasonable means (e.g., following up on published abstracts) can be used to track down unpublished studies. Prospective trial registries is probably the best way to circumvent publication bias and publication lag because, as new trials become registered before they are started, the decision to register a trial cannot be affected by the result of the study, which is not yet known.

A well-rounded, thorough review on publication bias has been published elsewhere.^[17] More recently, an up-to-date volume on publication bias in meta-analysis provides comprehensive coverage that includes the following: different types of publication bias, mechanisms that may induce them, empirical evidence for their existence, statistical methods to address them, and ways they can be avoided.^[18] This edited volume features worked examples

with common data sets and explains and compares available software used for analyzing and reducing publication bias.

A final criticism against meta-analysis centers on its internal validity in that it cannot correct the qualitative flaws of the studies that it includes and thus it carries along the biases inherent in each included trial. As a careful meta-analysis identifies the quality defects of the individual trials; however, the identification of bias becomes one of the prime benefits of a systematic meta-analysis. Several scales on assessing the quality of randomized trials in meta-analyses have gained currency, such as the ones developed by Chalmers et al.^[19] and Jadad et al.^[20] A comprehensive bibliography of quality assessment methods has been published.^[21] So far, there is little evidence that the magnitude of the treatment effect corresponds to the quality of the studies.

An investigation of 25 scales for quality assessment found that the type of scale used to assess trial quality could result in different conclusions.^[22] Because the use of summary scores to identify trials of high quality can be problematic, it has been suggested that relevant methodological aspects should be assessed individually and their influence on effect sizes explored.^[22] By focusing attention on the quality of clinical trials, meta-analysis has probably provided a powerful stimulus for improving their conduct and their reporting.^[23]

STATISTICAL ANALYSIS FOR DISCRETE DATA

This section emphasizes the main statistical methods of meta-analysis that have been used when a study's results come from a 2×2 contingency table with two treatment groups and a binary outcome, a situation common in randomized therapeutic trials. A compendium of methods for combining discrete data can be found in *The Handbook of Research Synthesis*,^[24] one of the most comprehensive books on statistical, as well as non-statistical, matters pertaining to meta-analysis. Examples are also provided there.

It is not advisable to simply lump the results of different studies together as if only one large study had been performed. Not only may the results of larger studies unduly overwhelm the results of smaller studies, but the overall results may be distorted. As shown in Table 1, the risk ratio (i.e., relative risk) for each study is the same (0.50). Yet

simply adding their results gives a misleading value (0.39), often referred to as Simpson's paradox. Correct methods of pooling would, of course, give a pooled risk ratio of 0.50.

Fixed-Effects and Random-Effects Models

Two types of models have been employed to appropriately adjust for the potential confounding effect of study. In the fixed-effects model, which leads to inferences only about the studies assembled, the true treatment effect is assumed to be the same across all studies and the only variability of treatment effect considered is within each study (i.e., within-study variability). In the random-effects model, which leads to inference about all studies from a hypothetical population, each study can have a different effect that is randomly drawn from a normal distribution and is positioned about a central value; in this model, not only within-study variability but also variability of treatment effects across studies (i.e., among-study variability) is considered.

The fixed-effects model weights each study by its sampling variability of treatment effect, which incorporates the number of events and sample size in each treatment group of a study. Along with weighting by this sampling variation, the random-effects model also weights each study by an overall estimate of the variability of true treatment effects across studies. Compared with the fixed-effects model, the random-effects model tends to give wider confidence intervals, which makes its statistical significance more conservative than the fixed-effects models.

In practice, important differences in the results between these two statistical models occur infrequently. The random-effects model should be used when heterogeneity of treatment effect is present—that is, when there is evidence that there is no single effect of treatment across studies (see the next section “Assessing Homogeneity of Treatment Effects”).

For combining discrete data from 2×2 tables on, for instance, survival status and two treatments, fixed-effects models that have been used to combine estimates of treatment effect across studies include (but are not limited to) the following: directly weighted pooled risk differences and pooled risk ratios;^[25] Mantel–Haenszel procedure for pooling odds ratios and pooling risk ratios;^[25] and Peto's method for pooling odds ratio.^[26] Analogous random-effects models include the DerSimonian–Laird method for pooling risk differences,^[27] pooling odds ratios^[28] and

Table 1 Fictional Results of Two Randomized Controlled Trials

Trial	Treatment group			Control group			Risk ratio
	Deaths	Number	Risk	Deaths	Number	Risk	
A	20	100	20%	40	100	40%	20/40 = 0.50
B	50	500	10%	20	100	20%	10/20 = 0.50
Total	70	600	11.7%	60	200	30%	11.7/30 = 0.39
							11.7/30 ≠ 0.50

Table 2 Statistical Methods of Pooling Treatment Effects from 2×2 Contingency Tables

	Risk difference	Odds ratio	Risk ratio
Fixed Effects Model	Directly Weighted	Mantel–Haenszel with RBG Peto	Mantel–Haenszel with GR Directly weighted
Random Effects Model	D & L	D & L	D & L

D & L: DerSimonian and Laird (From Ref. [27])

RBG: Robins-Breslow-Greenland variance estimator (From Ref. [25])

GR: Greenland-Robins variance estimator (From Ref. [25])

pooling risk ratios,^[29] all of which add to the fixed-effects models an extra variance component of between-study variability of treatment effects.

Table 2 compartmentalizes these methods for pooling results from different studies. Programs, publicly available without charge, to analyze such data include Meta-Analyst,^[30] MIX,^[31,32] and Revman.^[33] We recommend that the user of such programs be fully familiar with the limitations of different formulas for calculating treatment effects and variances. For example, the Peto method may be biased if the allocation ratio of patients in the study arms is far from 1.^[34]

If person-time were used instead of number of persons in the denominator of a rate in a study, formulas for computing the incidence rate ratio and incidence rate difference of a study—along with how to pool them with a fixed-effects model—have been documented.^[25] Corresponding methods of pooling for a random-effects model are the same as those for a fixed-effects model but add between-study variability of treatment effects.^[29] For continuous data, pooled effect sizes exist for fixed-effects models^[35] and random-effects models.^[36]

We delineate the steps and formulas to derive the pooled risk ratio, a common measure used to combine the results of prospective trials, in **Table 3** with the directly weighted fixed-effects approach^[25] and in **Table 4** with the DerSimonian–Laird (random-effects) approach.^[27,29] The directly weighted fixed-effects approach is essentially the DerSimonian–Laird method with no interstudy variability of treatment effect (i.e., $\tau^2 = 0$ in **Table 4**).

Assessing Homogeneity of Treatment Effects

A few of the several ways of measuring heterogeneity are highlighted here. A chi-square test of homogeneity (or, some may say, heterogeneity) is used to test whether there is evidence that the treatment effects are different across studies.^[37] Step 1 of **Table 4** shows a chi-square statistic to assess whether the risk ratios are different across studies. The issue is not whether differences exist, for the population treatment effects of different studies are not expected to be identical, but whether they can be reasonably ignored. Given the low power of the chi-square test of homogeneity, as an arbitrary rule of thumb, P -values at or below 0.1 can usually be taken to mean that the differences should not be ignored. However, in most typical applications of

Table 3 Steps in Computing an Estimate and 95% Confidence Interval of a Pooled Fixed-Effects Risk Ratio

1. Compute natural logarithm of the risk ratio for the i th study ($i = 1, \dots, n$ total studies):

$$\ln(RR_i) = \ln(TR_i/CR_i)$$

2. Compute its standard error:

$$se_i = \left[\frac{b_i}{a_i(a_i + b_i)} + \frac{d_i}{c_i(c_i + d_i)} \right]^{1/2}$$

3. Compute the fixed-effects weight for each study:

$$w_i = 1/(se_i)^2$$

4. Compute the pooled natural logarithm of the fixed-effect risk ratio:

$$\ln(RRf) = \frac{\sum w_i \ln(RR_i)}{\sum w_i}$$

5. Compute its antilogarithm to obtain the pooled fixed-effects risk ratio:

$$RRf = e^{\ln(RRf)}$$

6. Compute the corresponding 95% confidence interval:

$$e^{\ln(RRf) \pm 1.96/\sqrt{\sum w_i}}$$

a_i = number of treated patients with the event of interest in the i th study ($i = 1, \dots, n$ studies)

b_i = number of treated patients without the event of interest in the i th study

c_i = number of control patients with the event of interest in the i th study

d_i = number of control patients without the event of interest in the i th study

$TR_i = a_i/(a_i + b_i)$ = the treatment rate in the i th study

$CR_i = c_i/(c_i + d_i)$ = control rate in the i th study

meta-analysis in biomedical fields, the number and size of studies is too limited and the chi-square test is thus underpowered. A non-significant result may not rule out heterogeneity.^[38]

As a function of the chi-square statistic of homogeneity (Q), the I^2 statistic is a descriptive measure that quantifies the extent of total variation in treatment effects across studies that is due to heterogeneity alone rather than chance;^[39,40] it is a kind of signal-to-noise ratio. It is computed as

$$I^2 = \left(\frac{Q - df}{Q} \right) 100\%,$$

where df refers to degrees of freedom, which equals the number of studies minus 1. Values on I^2 can range from 0–100%. Proposed benchmark values on I^2 of 25%, 50%,

Table 4 Steps in Calculating an Estimate and 95% Confidence Interval of a Pooled Random-Effects Risk Ratio

1. Calculate the homogeneity test statistic for the underlying risk ratios:

$$Q = \sum w_i [\ln(RR_i) - \ln(RR_f)]^2$$

Note: The null hypothesis is that the n underlying risk ratios are equal.

For hypothesis testing, this test statistic (Q) is compared with a given percentile (for example, 90th) of a chi-square distribution with $n - 1$ degrees of freedom.

2. Calculate the interstudy variability of treatment effects:

$$D = \frac{Q - (n - 1)}{\sum w_i - \frac{\sum w_i^2}{\sum w_i}}$$

$$I^2 = D \text{ if } D > 0 \text{ or } I^2 = 0 \text{ if } D \leq 0$$

3. Calculate the random-effects weight for each study:

$$w_i^* = [I^2 + (1 / w_i)]^{-1}$$

4. Calculate the pooled natural logarithm of the random effects risk ratio:

$$\ln(RR^*) = \frac{\sum w_i^* \ln(RR_i)}{\sum w_i^*}$$

5. Calculate its antilogarithm to obtain the pooled random effects risk ratio:

$$RR^* = e^{\ln(RR^*)}$$

6. Calculate the corresponding 95% confidence interval:

$$e^{\ln(RR^*) \pm 1.96 / \sqrt{\sum w_i^*}}$$

Definition and calculation of terms not appearing here appear in Table 3.

and 75% might be considered low, medium, and high, respectively. The I^2 statistic is viewed as a measure of inconsistency across the findings of the studies. A caveat about the I^2 is that with a limited number of studies, it tends to have large uncertainty. The 95% confidence intervals of I^2 can be readily estimated and are useful to convey the extent of uncertainty.^[41] One may also formally examine in sensitivity analyses the impact of specific studies on the extent of estimated between-study heterogeneity.^[42]

The Galbraith plot,^[43] a plot of the z-score of treatment effect versus the square root of the weight for each trial, is a convenient graphical technique to examine heterogeneity of effects. The L'Abbe plot,^[44] a plot of the treatment rate against the control rate, is another graphical technique to explore such heterogeneity. An empirical assessment of treatment effect and heterogeneity across 125 meta-analyses revealed that, while summary odds ratios and risk differences tended to agree in statistical significance, risk differences usually displayed more heterogeneity than odds ratios.^[45]

Meta-Regression Analysis

Meta-regression analysis^[46,47] is sometimes used as part of a meta-analysis to describe how a treatment effect may vary

with patient and study characteristics. Meta-regressions have been applied to several clinical areas.^[47–51] In a meta-regression of summary data, the unit of analysis is the individual study in the meta-analysis. Aggregate quantities reported in the studies, such as the mean dosage, mean age, and mean duration of disease, could be extracted and used as independent variables. The treatment effect (e.g., the risk difference) can be the dependent variable.

Taking the natural logarithm of a treatment effect measured on a multiplicative scale, such as the risk ratio and odds ratio, is suggested to help ensure that the dependent variable becomes normally distributed in order to make valid statistical inferences. It is more desirable to weight each study in the meta-regression proportional to its precision (e.g., the inverse for the variance of a study's treatment effect) rather than weighting the studies equally. When output is taken from certain standard statistical packages, like the Statistical Analysis System (SAS; Ref. [52]), is used to obtain the standard error of a regression coefficient, this standard error should be adjusted by dividing it by the square root of the mean squared error, as is appropriate for inverse-variance weighted least squares regression.^[46] Though potentially informative, the results of meta-regression based on covariates with aggregate numbers (e.g., group averages) do not necessarily prove causality and should be interpreted as cautiously as other ecological investigations when making inferences to individual patients.^[53,54] There are many caveats in the application of meta-regressions in practice, and these are discussed more extensively elsewhere.^[55,56]

STATISTICAL ANALYSIS FOR CONTINUOUS DATA

Characterizations based on fixed and random effects, assessment of homogeneity of treatment effects, and meta-regression analysis described above for discrete data also pertain for continuous data. In this section, a common statistical approach is highlighted for pooling summary estimates of continuous data for the difference between two treatment groups. This approach combines mean differences in the original units of the variable of interest. Details and examples on this approach are found elsewhere,^[24] as are combining standardized mean differences and combining correlations.

Fixed-Effects Model

Under the fixed-effects model, all estimates measure a common treatment effect and differences among these estimates are due to chance. Suppose that the data to be combined arise from a series of n independent studies. Let T_i be the mean difference between treatment and control group means in the i th study, and let $S^2(T_i)$ be the sample variance of T_i . Algebraically,

$$T_i = \bar{X}_i^t - \bar{X}_i^c$$

and

$$S^2(T_i) = S_{pi}^2 \left(\frac{1}{n_i^t} + \frac{1}{n_i^c} \right)$$

where, for the i th study, S_{pi}^2 is the estimated pooled common variance found in introductory statistics books, and n_i^t and n_i^c denote the sample sizes in the treatment and control groups, respectively.

The weighted average effect over the n studies becomes

$$\bar{T}_c = \frac{\sum_{i=1}^n w_i T_i}{\sum_{i=1}^n w_i}$$

where

$$w_i = \frac{1}{s^2(T_i)}$$

represents the weights that are inversely proportional to the sample variance in each study and that minimize the sample variance of $\bar{T}_c$, which is

$$S^2(\bar{T}_c) = \frac{1}{\sum_{i=1}^n \frac{1}{s^2(T_i)}}$$

The 95% confidence interval of the true treatment effect then becomes

$$\bar{T}_c \pm 1.96[S^2(\bar{T}_c)]^{1/2}.$$

If the confidence interval does not contain zero, the null hypothesis of a population treatment effect of zero gets rejected at the 0.05 level of significance.

Random-Effects Model

Regardless of whether a fixed-effects or random-effects model is employed, a test should be made about the assumption that the studies share a common treatment effect. This assumption can be tested with the following homogeneity test statistic:

$$Q^* = \sum_{i=1}^n w_i (T_i - \bar{T}_c)^2$$

In general, if Q^* exceeds the upper-tail critical value of the chi-square distribution with n minus 1 degrees of freedom, the observed variance across treatment effects is significantly greater than what would be expected by chance if all studies shared a common effect.

A random-effects model would incorporate an estimate of the between-study variance component:

$$S_T^2 = \frac{Q^* - (n-1)}{\sum_{i=1}^n w_i - \frac{\sum_{i=1}^n w_i^2}{\sum_{i=1}^n w_i}}$$

The computations follow those for the fixed-effects model except that the revised variance estimate

$$S^{2*}(T_i) = S_T^2 + S^2(T_i)$$

replaces $S^2(T_i)$.

BASIC STEPS IN PERFORMING AND EVALUATING A META-ANALYSIS

Though important, statistical analysis is only one facet of a comprehensive meta-analysis. A properly conducted meta-analysis can be most demanding and requires the utmost advanced planning and care in its conduct. Fig. 1 depicts the basic steps to perform a retrospective meta-analysis.

Fig. 1 Basic steps in performing a meta-analysis

Quantitative methods give an aura of credence to any analysis. A meta-analysis, similar to any clinical study, must be read carefully, recognizing its strengths and limitations. Guidelines are available on how to approach the scientific quality of a meta-analysis,^[57–59] although there is no full consensus on how to do this even among experts. There is some wider acceptance of the need for reporting standards, as exemplified by the QUORUM and PRISMA recommendations.^[7,23] In general, to assess quality, the following questions may be posed:

- a. Objectives: Were the objectives clearly stated, clinically useful, and well-formulated? Was the design of the meta-analysis addressing a well-specified population and clinical question?
- b. Identification and Selection of Studies: How were the studies selected? Were the inclusion criteria explicit? Which studies were excluded? Why? Were unpublished papers sought and their impact examined? How many sources of data were screened (e.g., electronic databases, meeting presentations, communications with experts and pharmaceutical sponsors)?
- c. Information about the Studies: Was information given on the specific study design, patient and disease characteristics, each treatment being compared, and study duration? What precautions were taken to avoid bias? What were the results of the individual studies? Were the clinical outcomes of the studies well-defined and useful? What criteria were chosen to appraise the quality of the studies?
- d. Methods of Analysis: What method was employed to combine the results? Was the method technically correct? Were confidence intervals, as well as *P* values, given? Was a fixed-effect model or a random-effect model used? Was there justification to combine the trials? Was a test of homogeneity of treatment effect performed? Were subgroup analyses defined a priori? Was sensitivity analysis used? Were meta-regressions performed to explore whether treatment effect was influenced by potential modifier variables? Was it considered whether the baseline disease risk of the patients affected the magnitude of the treatment effect?
- e. Results and Conclusions: Were the results interpreted cautiously? Were the conclusions justified by the data? What was the generalizability (external validity) of the included studies and the meta-analysis? Were limitations of the meta-analysis mentioned?

APPLICATIONS

Numerous applications appear in the literature on how the results of meta-analyses of pharmaceuticals have helped to determine optimal therapeutic use and to enhance the understanding of pharmaceuticals with respect to their

efficacy, safety, and cost-effectiveness. We highlight some of these applications, classifying them by a methodological framework.

Cumulative Meta-Analysis vs. Expert Opinion

Cumulative meta-analysis is a method of updating previous meta-analyses with the appearance of new studies.^[60] The method allows the monitoring of developing trends of therapeutic efficacy. When performed routinely, the earliest time when statistical significance is reached (by whatever criterion is chosen) can be identified.

The first placebo-controlled randomized study of a thrombolytic drug in the treatment of acute myocardial infarction was reported in 1959. A cumulative meta-analysis on this treatment (Fig. 2) could have found that in 1973, after eight studies included 2,432 patients, a statistically significant reduction in overall mortality of about 25% had been achieved with thrombolytic drugs relative to placebo (Mantel–Haenszel odds ratio = 0.74, 95% confidence interval, 0.59–0.92).^[61] Yet 62 more placebo-controlled trials were reported subsequently, involving an additional 45,000 patients. The Federal Drug Administration (FDA) did not approve a thrombolytic drug for this indication until 1988, 15 years after cumulative meta-analysis indicated that the treatment could have been found effective in saving lives. Compared with the results of the cumulative meta-analysis, expert opinions lagged substantially in recognizing the efficacy of the treatment and did not begin to recommend it until around the time of FDA approval.

Meta-Analysis in Cost-Effectiveness Analysis

Pooled estimates from a meta-analysis could serve as input into a decision analysis or a cost-effectiveness analysis. For example, a cost-effectiveness of enoxaparin, a low-molecular weight heparin derivative, was compared with low-dose warfarin in the prevention of deep-vein thrombosis (DVT) after total hip replacement.^[62] To determine the proportion of DVT with enoxaparin and warfarin prophylaxis, the authors pooled the proportions from the available studies to arrive at the efficacy of the drugs as input into determining that the incremental cost-effectiveness of enoxaparin relative to warfarin was estimated as \$29,120 per life-year gained (in Canadian dollars).

Meta-Analysis for Optimal Dosing

A meta-analysis of 35 randomized placebo-controlled trials was undertaken to study the efficacy and safety of different aspirin dosages for patients at high risk of vascular disease.^[49] Dose-response meta-regressions indicated no evidence that lower doses of aspirin were more efficacious or less efficacious in preventing overall mortality and vascular events. There was evidence, however, that lower doses of aspirin significantly reduced gastrointestinal

Fig. 2 Cumulative meta-analysis of thrombolytic therapy vs. placebo for acute myocardial infarction. Note: The cumulative meta-analyses by year of publication of randomized controlled trials (RCTs) are presented on the left. The cumulative number of trials and patients (Pts) are also presented. On the right, the recommendations of the clinical expert reviewers are presented in two-year segments, except for the entry in 1966, which represents all previous years (From Ref. [61].)

symptoms. For a daily dosage increase of 100 milligrams of aspirin, the (unadjusted) odds ratio of gastrointestinal symptoms increased by 4.5% on average (99% confidence interval, 1.83–7.25%).

Aminoglycosides are one of the most commonly used antibiotics for serious infections. There are several agents in this class with very similar mechanism of action and toxicity profile. The drugs have traditionally been administered with multiple doses a day, although experimental evidence would suggest that giving the whole daily dose in a single daily administration should be as efficacious and possibly less toxic. Twenty-one trials were used to compare single versus multiple daily doses of aminoglycosides. A meta-analysis of these trials convincingly showed that single daily doses were about 25% less nephrotoxic than and at least as efficacious as multiple daily doses.^[50] These findings are expected to result in better outcomes, substantial cost savings, and increased convenience.

Many randomized controlled trials addressed the efficacy of many different regimens in the prophylaxis of *Pneumocystis carinii* infection among patients with advanced human immunodeficiency virus infection. A meta-analysis of 35 randomized trials showed the marked superiority of trimethoprim-sulfamethoxazole regimens over aerosolized

pentamidine and dapsone.^[51] The meta-analysis predicted a 43% reduction in the odds of discontinuations of prophylaxis due to side effects when trimethoprim-sulfamethoxazole was used at a lower dose (one double strength tablet three times a week) instead of the regular dose (one double strength tablet daily), with no substantial loss of efficacy.

Meta-Analysis for Bioequivalence

Under current FDA regulation, a patient may switch from a brand-name drug to a generic drug if they are shown to be bioequivalent. Bioequivalence between generic copies of the brand-name drug, however, is not required by the FDA. Chow and Liu^[63] have proposed a methodology to provide an overview on the assessment of (average) bioequivalence among approved generic copies of an expired brand-name drug. Their methodology was intended to help guide the FDA and others in evaluating the bioequivalence among the approved generic copies. More work is needed in this area.

In general, meta-analysis has been gaining recognition by FDA. Although it is frequently used in issuing warnings and treatment guidelines, though, large and randomized clinical trials continue to be relied on and necessary for approval.

Drug Planning and Development

Perhaps the most fruitful applications of meta-analysis in the years to come are in the prospective planning of drug and therapeutic strategy development. Current drug development typically is trying to meet the regulatory mandates for showing treatment efficacy and safety, and is also largely dictated by piecemeal planning and clinical opportunities for the drug. Prospective meta-analysis offers a framework for building all the trials in the development of a drug within a single matrix with explicit quantitative plans for the analysis and interpretation of the complete accumulated evidence. This approach will alleviate the threat of publication bias and will instill full transparency and credibility to the results of developmental trials seen in their totality. On an even larger scale, prospective meta-analysis matrices may incorporate different drugs for the same disease or indications. Such prospective meta-analyses are one of the most appealing challenges of current therapeutics. Some current research addresses specifically the possibility to design new trials based on the appraisal of prior evidence to see what types of comparisons are missing^[64] and how big future studies should be.^[65]

SOME KEY DEVELOPMENTS

There have been a multitude of recent developments in meta-analysis and the field has been a fertile area for statistical and epidemiological research. We highlight three major developments here.

Control Rate

For a dichotomous outcome, the control rate is the proportion of patients in the control group with the event of interest. The control rate in a clinical trial has gained acceptance as an available summary measure of patient or study differences that may help to explain the heterogeneity of treatment effects across studies.^[66–68] The control rate is a summary measure that is usually reported. Variation in control rates across studies may reflect different patient populations, underlying baseline risk of patients, length of study follow-up, and treatment delivery. As a readily available simple measure to explore treatment effect heterogeneity, the control rate may help delineate when one needs further research on risk factors.

The size of the treatment effects of studies in a meta-analysis may tend to vary with the size of the control rates in these studies. Several methodological advances have been made in this area.^[69–73] For example, in an empirical investigation that analyzed 112 meta-analyses, Schmid et al.^[73] used a hierarchical model to find that the control rate was significantly associated with the risk difference in 35 meta-analyses (31%), with the risk ratio in 15 instances (13%), and with the odds ratio in 16 (14%). The impact of

differing patient risks on the results of clinical trials, along with the advantages and limitations of using the control rate as a measure of baseline risk, have been discussed.^[74,75]

Large Trials and Meta-Analyses

The extent of concordance between the results of large trials and the results of meta-analyses of smaller trials on the same topic has stirred considerable debate. Three different groups of investigators evaluated and compared these results. Villar et al.^[76] found moderate agreement, beyond chance, between results of large trials and those of smaller trials. Cappelleri et al.^[77] concluded that the results of the two methods usually agree, but discrepancies do occur; however, clinically important discrepancies without an obvious explanation were unusual. LeLorier et al.^[78] concluded that up to 35% of the time a meta-analysis failed to predict accurately the results of a subsequent, large trial.

In their evaluation of the three protocols, Ioannidis et al.^[79] concluded that a comparison of large trials with meta-analyses may reach different conclusions depending on the design used, the studies selected, and the method of analysis employed. When a robust approach was used that accounts for both the magnitude and the uncertainty of treatment effect, the estimated range of disagreements was fairly similar in the three protocols (10–23%). Future clinical trials may benefit in addressing sources of heterogeneity of treatment effect between large trials themselves and even within a large trial. Similarly, future meta-analyses may benefit in addressing sources of heterogeneity rather than try to always fit a common estimate among diverse studies.

Meta-Analyses of Individual Patient Data

Most meta-analyses in the past have been conducted using summary, or aggregated, data on treatments and subgroups from clinical trials. Meta-analyses of individual patient data (MIPD) offers several distinct advantage of performing more detailed analyses using all the data on each individual patient participating in a clinical trial to be included in meta-analysis. This may allow, with the use of regression analyses, for detailed time-to-event analysis, the development of more accurate predictive models for the risk of the studied outcome, and the quantification of different treatment effects for different subgroups. Furthermore, the process of performing MIPD may also improve the quality of trials by revealing additional issues that cannot be gleaned from published reports. Stewart and Clarke^[80] provided a description of the organizational steps required for performing a MIPD. Increasingly, applications using MIPD from randomized trials, as well as from observational studies, have burgeoned in different therapeutic areas.^[81–84]

The results of MIPD against meta-analyses on group data give similar, if not identical, findings for the main effect of treatment when no covariates are in the model. They may

not necessarily give similar results or even similar conclusions with regard to modification and heterogeneity of treatment effect for different levels of a covariate.

For instance, in a survey of group-level and individual patient-level data from five randomized trials on the benefits of anti-lymphocyte antibody induction therapy among renal transplant patients, Berlin et al.^[85] found that the treatment was significantly more efficacious among patients with elevated levels (20% or more) panel reactive antibodies than among patients without such levels based on the individual-patient analysis; the group-level analysis failed to detect this interaction. The authors concluded that individual patient data should be used, when feasible, to study patient characteristics in order to avoid the potential for ecological bias introduced by group-level analyses.

Schmid et al.^[86] conducted two investigations to evaluate Bayesian meta-regression for detecting treatment interactions. The first investigation involved the comparison of aggregate and individual patient data on 1,860 subjects from 11 trials testing angiotensin converting enzyme inhibitors for nondiabetic kidney disease; the second explored meta-regression for detecting treatment interaction 671 covariates, including the baseline risk from 232 meta-analyses of binary outcomes. These authors concluded that meta-regression can detect interaction of treatment with study-level factors when treatment effects are heterogeneous, and that individual patient data are needed for patient-level factors and homogeneous effects.

Discrepancies may arise when different data are used by the MIPD and the meta-analysis of group data (such as updated information beyond the main trial follow-up in the MIPD). Disadvantages of MIPD include the fact that it requires more effort and coordination on an international level, and the potential for retrieval bias when individual patient data can be retrieved only for a selected group of the pertinent trials.

Nevertheless, meta-analysis of individual patient data may present the highest step in the hierarchy of evidence.^[87] The statistical methods for synthesis at the patient level are, to a large extent, similar to those used in the analysis of multicenter clinical trials. The main feature that differentiates MIPD from a single trial is that a covariate can be included at the study level, with the effect of the covariate on outcome being either fixed or random and possibly made to depend on other factors. To learn more about the advantages and disadvantages of systematic reviews using individual patient data, the reader can consult Stewart and Tierney.^[88]

Methodological research on MIPD is well-suited to examine possible heterogeneity of treatment effect with both patient-level and study-level covariates in multi-level models. The use of prognostic scores derived from MIPD, for example, may help to better explain a possible relationship between underlying risk and treatment effect. Moreover, when MIPD is available only from a proportion of known studies, combining MIPD with aggregate data can

lead to more complete information. For more information on using multilevel (hierarchical) models for these purposes, the reader is referred to Goldstein et al.,^[89] Turner et al.,^[90] and Sutton et al.^[91]

Cumulative Meta-Analysis

Cumulative meta-analysis, which has been used to illustrate important gaps between accumulated evidence and the behavior of researchers and practitioners, typically involves performing an updated meta-analysis when a new trial or trials are added to a series of similar trials, which by definition involves multiple inspections. Neither the commonly used random effects model nor the conventional group sequential method can control the type I error for many practical situations.

In addressing this problem, Lan et al.,^[92] for the case of continuous outcomes, and Hu et al.,^[93] for the case of binary outcomes, invoked the Law of Iterated Logarithm (LIL) to “penalize” the Z-value of the test statistics to account for multiple tests and for the estimate of heterogeneity in treatment effects across studies. The LIL method involves an adjustment factor that is directly related to the control of type I error and determined through extensive simulations under various conditions. The LIL method controls the overall type I error for a broad span of practical situations with a binary outcome or continuous outcome; the LIL works properly in controlling the type I error rates as the number of inspections becomes large.

Other researchers have made refinements and extensions to cumulative meta-analysis.^[94–97]

Indirect Comparisons

Although the randomized controlled trial is the most valid design for comparing the efficacy of interventions, many competing interventions have not been compared in randomized controlled trials (or, if compared, scantily so) and indirect methods have been used instead for medical evidence and policy decisions.^[98,99] Suppose, for example, that Treatment A is directly compared with Treatment B, and Treatment B is directly compared with Treatment C, across several studies. Although no direct comparison can be made here between Treatment A versus Treatment C, an indirect comparison can be between them. Such indirect comparisons, though, are generally subject to greater bias than head-to-head comparisons, as the data of interest are not available; therefore, it is essential to promote research that evaluates such bias, which may distort the estimate of treatment effect and, in doing, lead to inappropriate decisions.

These so-called mixed treatment comparisons can be viewed as an extension of traditional meta-analysis to which all possible treatment options can be compared. Consider two simple ways to indirectly compare two treatments A and B: (i) combine all A arms and combine

all B arms and (ii) use A versus C arms and B versus C arms as additional evidence. The latter, but not the former, approach preserves randomization and within-study comparisons. For this latter method, the difference in the treatment effect between respective pairs of treatment (A and C against B and C) gives an (indirect) estimate of the treatment effect between A and B. This indirect comparison, however, involves an assumption of coherence: that the treatment effects from indirect comparisons should be the same as the treatment effects from direct comparisons.

In addition to respecting the randomization of the included trials, Bayesian Markov Chain Monte Carlo (MCMC) methods and network meta-analysis can provide an efficient way to combine data for indirect comparisons, acknowledge their extra variability, and examine the plausibility of assumptions.^[100–107] These methods also yield probability statements on how likely each treatment is to another and, as such, enhance interpretation of results and overcome the difficulty created by multiple comparisons. Time will tell whether the MCMC methodology will become mainstream to assess treatment efficacy.

Other Developments: Methods, Software, Education

Numerous other developments on meta-analysis have been made on methodological, computational, and educational fronts. Some methodological advancements include (but are not restricted to) those on publication bias,^[18] Bayesian approaches,^[108] longitudinal analysis,^[109] survival analysis,^[110] and a general multivariate approach to meta-analysis.^[111] Sutton and Higgins^[112] have compiled a thorough, wide-ranging review on recent development in meta-analysis, which include the following: heterogeneity and random-effects analyses, special considerations in different areas of application, an assessment of bias within and across studies, and an extension of ideas to complex or nonstandard evidence synthesis.

Advances in software programs dedicated to meta-analysis have made statistical computing of pooled data more accessible and powerful.^[113] Among the most highly rated of them are the commercially available Comprehensive Meta-Analysis^[114] and freely available MIX.^[31,32] Among the general-purpose programs, the freely available BUGS for Windows^[115] and the commercially available SAS^[52,109,111,116–118] and STATA^[119] are among the most comprehensive. A spreadsheet application like Microsoft Office EXCEL is well-suited to handle basic calculations.^[120] The freely available MetaEasy is a meta-analysis add-in for Microsoft EXCEL.^[121]

Many instructional articles and textbooks have appeared, especially over the last dozen years, to enrich and expand one's knowledge of meta-analysis.^[18,24,109,111,118,120,122–133]

CONCLUSIONS

Meta-analysis may be defined as the statistical analysis of data from multiple studies. A meta-analysis typically identifies data systematically, summarizes results, and evaluates quantitatively sources of heterogeneity and bias. This chapter has highlighted the benefits and limitations of meta-analysis. Common statistical methods were described for pooling discrete data from 2×2 contingency tables and for pooling continuous data from multiple studies. Basic steps to perform and evaluate a meta-analysis of randomized therapeutic trials were featured. Several applications of meta-analysis were highlighted. Some of the major methodological developments and resources for further reading were noted.

Abstract

Microarray is a device for measuring transcription abundance of a large number of genes simultaneously under experimental conditions. This entry discusses microarray technology and experimental designs, and also touches on sample size estimation.

Keywords: Classification and prediction; Clustering analysis; Experimental design; Gene Selection; Gene set analysis; Matrix map, Sample size; Visualization.

INTRODUCTION

A gene consists of a segment of deoxyribonucleic acid (DNA). A DNA molecule is a double-stranded polymer composed of four basic molecular units called nucleotides. The expression of genetic information stored in the DNA molecule occurs in two stages: (i) transcription, during which DNA is transcribed into mRNA (messenger ribonucleic acid), a single-stranded complementary copy of the base sequence in the DNA molecule; and (ii) translation, during which mRNA is translated into protein, which are action molecules of the cell responsible for nearly all cellular processes. The majority of genes are expressed as the protein they encode. Although regulation of protein synthesis is not solely controlled by mRNA levels, the changes in protein abundance are determined in part by changes in the levels of mRNA. By measuring transcription levels of genes in an organism under various conditions, at different developmental stages and different tissues, one can characterize the dynamic function of each gene in the genome. DNA microarray is a device for measuring transcription abundance of a large number of genes simultaneously under experimental conditions.

DNA microarray technology provides tools for studying the expression levels of a large number of distinct genes simultaneously.^[1] The technology is based on the hybridization of known DNA segments on the array with an unknown labeled DNA or RNA sample based on base-pairing rules. Gene expression levels are quantified from the image of a hybridized microarray excited by a

laser scanner. Signal intensities reflect the amount of transcript present for the gene in the mRNA sample. A typical microarray experiment data set includes expression levels of thousands of genes in a number of experimental samples (conditions). These samples may correspond to different toxins or serial time points taken during a biological process. The expression data can be summarized by a matrix with rows representing genes and columns representing samples. This matrix is referred to as a gene expression matrix. A gene expression matrix can be analyzed by comparing expression profiles of an individual gene (row) under various conditions or comparing expression profiles of a sample (column) to understand their similarities and differences and to find the relationships among genes and sample conditions.

DNA MICROARRAY EXPERIMENT

A microarray experiment is a multi-step process, where each step is potentially a source of variation. Usually, raw data generated from image analysis cannot be directly compared. Data need to be normalized in order to minimize systematic biases so that biological differences can be distinguished. Statistical analyses generally are of two types. The first type of analysis involves identification of the genes that are differentially expressed among different sample groups. The second type seeks to determine the relationships between genes or gene clusters to identify biological functions, or to predict specific biological outcomes (or diseases) from the analysis of expression patterns. Many statistical methods are used in microarray data processing and analysis. Microarray technology, experimental design, data preprocessing and normalization, significance

testing, classification and prediction, and cluster analysis and pattern recognition are discussed in the following sections.

MICROARRAY TECHNOLOGY

cDNA Microarray

A cDNA microarray consists of thousands of single-stranded known DNA fragments attached at fixed spots by a robotic arrayer. The known DNA fragments are selected from a cDNA library prepared from reverse transcription of mRNA from various tissues and organisms. Ideally, each gene fragment should represent a unique gene or alternative splice variant. There are rat, mouse, and human arrays commercially available. Additionally, tissue-specific arrays can be constructed from a cDNA library extracted from the tissue.

In the experiment, the mRNA extracted from the tissue cell sample under study is purified, reverse transcribed into cDNA target, and labeled with green or red fluorescent dyes for the treatment or reference sample, respectively. Labeled cDNA hybridizes to the spots containing complementary sequence probes on the array based on base-pairing rules. After hybridization, the fluorescent signal intensities are imaged using a scanner. Two intensities, one for each dye, are measured on each spot. The intensities are considered as surrogates for the expression levels of genes in the sample under study. Some experiments may use only a single fluorescent dye approach; therefore, one intensity is measured on each spot.

The process of transforming the fluorescence intensity of each spot into a measure of transcript abundance is referred to as image analysis. In addition, image analysis includes evaluation of the quality of the quantified spot intensities and flagging unreliable spots or arrays. Image analysis can be separated into three steps: (i) image acquisition, (ii) spot location, and (iii) intensity extraction. First, the microarray is scanned to produce two images, one for each color. These images are stored as a 16-bit tag image file format (TIFF) file (a digital record of fluorescence intensities of pixels for the array), representing a number between 0 and $2^{16}-1$. As soon as the image has been captured, the next step is to locate each spot on the array. This can be performed automatically by the image analysis software. The image analysis software must segment the pixels as foreground (feature) or background. Once the foreground pixels and background pixels have been identified, the spot intensities are calculated using the mean (or median) intensity of all foreground pixels and, subtracting from them the mean (or median) intensity of the background pixels. The adjusted intensities are the primary data for subsequent analyses. The background-corrected intensity may be negative for some spots. Fig. 1 depicts the scheme of a two-color microarray experiment.

Fig. 1 Two-color DNA microarray experiment

Oligonucleotide Microarray

The oligonucleotide array technology was introduced by Lockhart et al.^[2] and Lipschutz et al.,^[3] and is commonly known as Affymetrix GeneChip™ (Santa Clara, CA). This technology does not use gene fragments extracted from a sequenced cDNA library as in cDNA microarray. Typically, each gene will be represented by 16 to 20 pairs of oligonucleotides referred to as probe sets. Each probe pair consists of 25 base sequences. One is perfectly complementary to a portion of a given transcript referred to as a perfect match (PM) probe. Each PM probe is paired with a mismatch (MM) probe that is created by changing the middle (13th) base pair to control for the possibility of cross-hybridization. RNA samples are prepared and labeled with fluorescent dye. Arrays are scanned, and images are produced to obtain an intensity for each probe. These intensities indicate how much hybridization occurred for each oligonucleotide probe. The level of expression of each gene is calculated as an “average” of the difference between PM and MM, via a procedure provided by Affymetrix through their scanning software. The Affymetrix array is regarded as a one-color platform.

The Affymetrix arrays are constructed on a silicon chip by photolithography and combinatorial chemistry. The target labeling is performed using amplified RNA rather than cDNA. Hybridization to the array is noncompetitive (only a single sample is applied to each chip), and is detected by addition of a fluorescently labeled streptavidin compound that binds to the biotin group in the aRNA molecules.^[4]

cDNA methods are more flexible in design. Researchers have control over the probe content on the array. It can be applied to any organism. The hybridization is based on over a thousand bases rather than 25 bases, thus reducing the chance of cross-hybridization artifacts. In contrast, oligonucleotide arrays can accommodate the genes not represented in a cDNA library. It has lower variability from chip to chip, and can be used by researchers for data comparison across research groups.

Other Microarray Technologies

Recently, a hybrid technology consisting of 50- to 80-mer oligonucleotides representing each gene was introduced. This technology combines the uniformity of GeneChip™ with the specificity of cDNA microarray. That is, the length of sequence is optimized to minimize cross-hybridization compared to shorter-length probes. Also, the oligo-array has higher sensitivity compared to cDNA probes.

Several other microarray-based techniques have also been introduced in recent years. Microarray-based comparative genomic hybridization (array-CGH)^[5,6] is one such technique by which variations in copy numbers between two genomes can be analyzed using DNA microarrays. Array-CGH detects genomic copy number variations more effectively at a higher resolution level than conventional chromosome-based comparative genomic hybridization (CGH). The CGH program developed by Lee et al.^[7] is a user-friendly array-CGH analyzing program that displays analyzed chromosomal data with a corresponding G-banding ideogram. The abnormal DNA copy numbers (gains and losses) can be identified automatically using a user defined window size and sequential student t-tests with sliding windows along with chromosomes.

EXPERIMENTAL DESIGN

A microarray experiment is generally a comparative experiment, in which the experiment of interest is the comparison of the relative expression levels among the samples rather than the determination of absolute intensity measures of each sample. Furthermore, the underlying principle of a two-color experiment is competitive hybridization between two samples. The measured intensities reflect the relative abundance of each sample. Data generated are inherently comparative. In a one-color experiment, the intensity is an absolute measure of gene expression; however, this measure should not be regarded as the precise measure of transcript abundance. Instead, inferences are made about the expression levels for a gene in different samples, not about the level of expression of one gene relative to other genes.

Variability, Replication, and Experimental Unit

The variation of the measured gene expression data can be generally classified into three categories: biological variation, technical variation, and residual variation.^[8,9] Biological variation refers to the variation that arises from different RNA sources, such as different animals or different cell lines or tissues. It reflects differences in host characteristics. Biological variation is due to inherent differences in gene expression, varying from subject to subject due to genetic or environmental factors. Biological variation is estimable only when there are independent

biological replicates. If all biological samples are pooled, the biological variation is minimized, and inference can be made only as to the experimental conditions. The sources of variation associated with the assay of mRNAs in each biological sample and array manufacture are collectively referred to as technical variation. The technical variation accounts for the variation associated with the use of microarray techniques unrelated to the biological samples. The residual variation accounts for sampling or experimental variation or other unaccountable factors. The biological, technical, and residual variations are mutually independent. The variation in a measured intensity is the sum of these three variations.

Experimental design methods are used to identify and minimize experimental variations and provide sound statistical inference. The basic principles of experimental design are randomization, blocking, and replication. Replication is essential in the experimental design. There are two types of replications:^[10] biological replication and technical replication. Biological replication refers to hybridizations that involve mRNA from different extractions. Biological replication is used to allow the generalization of experimental results from sample to population. Technical replication refers to replication in which the mRNA is from the same pool (the same extraction). Technical replication is used to minimize technical artifacts. In microarray quality control experiments, technical replication may be used to assess laboratory or platform reproducibility.

In most microarray experiments, the experimental unit refers to an independent biological RNA source to which the treatments are applied. The experimental unit may be represented by a tissue sample or a sample of cells from a cell culture. The array is not the experimental unit. However, in many studies, an array and an experimental unit have a one to one correspondence, so the array is not distinguishable from the experimental in such studies.

Types of Experimental Design

The choice of experimental design depends on the number of different samples to be compared as well as the aim at the comparisons of interest. Experimental design for one-color microarray experiments such as Affymetrix oligonucleotide array is similar to clinical trials or other biological experiments. The same principle used in the biomedical experiment can be applied to microarray experiments. For example, the biological samples (experimental units) should be randomized to a treatment using a pre-determined scheme. Blocking can be used to increase the precision of estimates. (A block is a subset of experimental units that are more homogeneous than the entire experiment itself.) In the two-color experiment, two samples are labeled differently for competitive hybridization. One important design issue is to determine which samples are to be labeled with a corresponding fluor, and which are to be hybridized together in the same array. In addition, there

can be constraints on the number of slides, the amount of RNA available, or cost considerations.^[9]

The simplest microarray experiment is intended to study the changes in gene expression levels between a control and a treated sample. Each microarray in the experiment is probed with two cDNA samples. The expression levels of the two samples can be compared for each gene in an array. In practice, however, the expression levels from the two measurements are not directly comparable because of dye effects. One dye may be consistently brighter than the other because of different labeling efficiencies, or different scanning sensitivities in the two dyes. Fig. 2,^[11] is a density plot (in log based-2 scale) of a same-same (control vs. control) array. That is, two control samples are labeled separately, one with Cy5 (red dye) and one with Cy3 (green dye). Also, the upper half and lower half of the array are duplicate. In Fig. 2, the solid lines represent the genes from the upper half, and the dotted lines represent the lower half. The dark and light curves represent the red and green fluorescent readings, respectively. The plots show that there were systemic location effect differences in dye intensity across the individual DNA probes. (The left tail from the low intensity spots represents the empty genes.)

To adjust for dye biases, the so-called dye-swap design with two arrays is often used. On array 1, the control

sample is assigned to the green dye, and the treated sample is assigned to the red dye; the dye assignments are reversed on array 2. Dye-swap design is a loop design (described below) for the experiment with a control and a treatment study. This design is useful to reduce dye biases, but it is unlikely to eliminate the bias in every spot of every array. Dye bias and variation can be reduced via the normalization method (see the section “Normalization”).

Many experiments involve more than one treatment sample. Each experiment will have its own study objectives. Some studies may be interested in the comparisons of differences in the expression profiles among different toxins or different cell lines. In other studies, different samples may come from different time points or different dose levels. The main objectives of these two types of studies can be different. Kerr and Churchill^[12] described the two designs for a single factor study: (augmented) reference design and loop design.

In the reference design, all samples of interest (control and treatments) are hybridized on different arrays labeled with the same color dye, while a reference sample labeled with the other color dye is used on every array to hybridize with either a control or a treatment sample. One can denote a dye assignment in which the first sample is labeled with red and the second sample labeled with green as R/G. A reference design for an experiment with four groups—T0, T1, T2, and T3—can be expressed as [T0/Ref, T1/Ref, T2/Ref, T3/Ref]. The reference sample (Ref) can be the same as the control sample (T0) or a universal reference sample. This design has several advantages. The experiment is easy to conduct. The relative expression levels of the treated to control can be directly computed as observed responses. Because each array consists of one measurement of relative change of the sample to a common reference for each gene, statistical methods are readily applicable. In this design, treatment effects are confounded with dye effects. It assumes there are no treatment $\times$ dye interaction effects.

Reference design can be inefficient because fully half of the data are dedicated to an extraneous sample. This type of design is an indirect comparison in which the reference sample serves as an intermediate between two treatments. Suppose the variance of a single log comparison, $\log(T_i/\text{Ref})$, is σ^2 , then the variance of the comparison $\log(T_i/T_j) = \log(T_i/\text{Ref}) - \log(T_j/\text{Ref})$ is $2\sigma^2$.

In the loop design, the control and each treated group are labeled once with the red and once with the green. A loop design for the four groups—T0, T1, T2, and T3—can be [T0/T1, T1/T2, T2/T3, T3/T0] or [T1/T0, T2/T1, T3/T2, T0/T3]. The loop design uses the same number of arrays as a reference design does, but it collects more information on the treatments. The loop design compares two adjacent treatments directly. The variance between two groups hybridized in the same array $\log T_i/T_{(i+1)}$ is σ^2 (but with only one array). Yang and Speed^[7] provided more details on the variance of reference design and loop design, and the time-course experiments and multifactorial designs.

Fig. 2 Density plot of a same-same array

Sample Size Estimation

A fundamental goal in microarray studies is to identify a subset of genes that are differentially expressed under experimental conditions of interest. Before conducting a microarray experiment, one important issue that needs to be decided is the number of arrays (replicates) required in order to have adequate power to identify differentially expressed genes. Lee et al.^[13] suggested three replicates in view of the noise-to-signal ratio. Statistical tests to determine the effects of a treatment on different biological populations should be based on the biological replicate samples. In many studies, an array and a biological sample have a one to one correspondence, the array is not distinguishable from the biological sample. Nevertheless, sample size estimation refers to the number of biological samples needed for the experiment to identify a treatment effect.

Sample size estimation for a single gene is formulated as the number of arrays needed in order to ensure the power $(1 - \beta)$ of detecting the mean difference δ (standardized effect size) at a pre-specified significance cutoff α , where the standardized effect size refers to the desired change of a gene to be detected divided by the estimated standard deviation. For the two sample t -test given α and δ , the number of samples needed in each group in order to achieve the desired power is $n = 2(t_{\alpha/2} + t_{\beta})^2/\delta^2$, where t_{α} and t_{β} are the corresponding percentiles of a t -distribution.

In microarray experiments, identification of differentially expressed genes involves multiple tests of many genes. Additional factors need to be considered: the total number of genes m , the (expected) number of truly differentially expressed genes m_1 (or the proportion of the differentially expressed genes $\pi_1 = m_1/m$), the standardized effect size δ of each gene, the correlation structure among genes, the multiple testing procedure to be used, and pre-specified levels of type I error rate and “power.” The parameters m , m_1 , and the (standardized) effect size $\delta = (\delta_1, \dots, \delta_{m_1})$ for all differentially expressed genes are pre-specified by the investigator. The type I error rate can be specified in terms of the family-wise error rate (FWE),^[14,15] false discovery rate (FDR),^[16–19] or comparison-wise error rate (CWE).^[19–22] The FDR q^* is commonly used in the microarray data analysis. The “power”^[14–23] is commonly referred to as the proportion of truly differentially expressed genes that are correctly declared, the sensitivity. The desired sensitivity is denoted as λ_0 . Given m , $\pi_1 (= m_1/m)$, and effect size $\delta = (\delta_1, \dots, \delta_{m_1})$, the sample size estimation commonly is formulated as the number of arrays needed to detect the specified sensitivity λ_0 , *on average*, at the specified type I error q^* . This formulation of sample size problem is inadequate because the probability of achieving the specified sensitivity can be lower than 50%.

Wang and Chen^[15] and Tsai et al.^[19] formulated the problem as the number of arrays needed to achieve the specified sensitivity λ_0 with a coverage probability ϕ_{λ_0} , where ϕ_{λ_0} is the probability that *at least* λ_0 proportion of

truly differentially expressed genes is detected. In this formulation both λ_0 and ϕ_{λ_0} need to be specified, they are not necessarily equal. The ϕ_{λ_0} can be set at 95%. Tsai et al.^[19] provided a method to estimate the needed sample size for the independent and constant effect size ($\delta_i = \delta_0$ for all i) model as follows.

Given α , δ_0 , and $(1 - \beta)$, the needed sample size n for detecting a differentially gene is

$$n^* = \frac{2(t_{\alpha/2} + t_{\beta})^2}{\delta_0^2} \quad (1)$$

Under the independent model, the total number of truly differentially expressed genes detected U is a binomial random variable with success probability $(1 - \beta)$. The probability ϕ_{λ_0} of identifying at least λ_0 fraction of m_1 differentially expressed genes is the sum of the binomial probabilities^[19]

$$\phi_{\lambda_0} = P(U/m_1 \geq \lambda_0) = \sum_{l=[m_1\lambda_0]}^{m_1} \frac{m_1!}{l!(m_1-l)!} (1-\beta)^l \beta^{m_1-l} \quad (2)$$

For specified q^* and λ_0 , sample size can be estimated by first solving for the constant comparison-wise power $(1 - \beta^*)$ from the equation,

$$\phi_{\lambda_0} = \sum_{l=[m_1\lambda_0]}^{m_1} \frac{m_1!}{l!(m_1-l)!} (1-\beta^*)^l \beta^{*(m_1-l)} \geq 95\%. \quad (3)$$

The calculated power $(1 - \beta^*)$ is then used to estimate the α level corresponding to the specified q^* , $\alpha = [m_1(1 - \beta^*)q^*]/[m_0(1 - q^*)]$. Subsequently, the sample size n is calculated from Eq. 1 by using α and $(1 - \beta^*)$.

Gene expression data are typically positively correlated, which leads to an over-dispersion (relative to the independence) on the distribution of the true positive findings. Therefore, the methods based on the independent model described above will underestimate the true needed sample size. Tibshirani^[22] proposed a permutation method to account for both dependency and unequal effect sizes among genes using a pilot data set. Because the sample size of the pilot data is typically smaller than the needed sample size, the null distributions generated from the pilot data have more variations; simply using the null distributions generated from the pilot data can overestimate the needed sample size. Recently Lin et al.^[23] proposed a permutation procedure modified from the Tibshirani^[22] method. Their method takes the correlation structure and effect size heterogeneity into consideration by using a small pilot data set, four to six samples per groups.

DATA PREPROCESSING AND NORMALIZATION

After data collection, many factors in generating intensity measurements need to be considered prior to data analysis.

There are low signal intensities or inconsistent spots across arrays. In addition, the intensities contain background contribution that can be addressed in diverse ways. Some arrays may have multiple probes that measure the same gene; the intensities from these probes can be combined to generate a single expression level for the gene. Data pre-processing is the first step of data analysis, it attempts to correct technical biases. There are many options and methods for data filtering, local and regional backgrounds, multiple probes, and normalization and transformation. In particular, normalization has been an active research area in microarray data analysis since the microarray technology was introduced.^[24–32] Normalization methods for the Affymetrix arrays have been proposed including dCHIP,^[29] RMA,^[30] Affymetrix Microarray Suite 5.0 (MAS 5), and Affymetrix Probe Logarithmic Intensity Error (PLIER) http://www.affymetrix.com/support/technical/technotes/plier_technote.pdf.

The primary goal of normalization is to properly eliminate or minimize the systematic variation, such as microarray construction in probe printing, sample preparation procedures, hybridization and washing procedures, detecting method, and so forth. Normalization strategies depend on the experimental design and the data collection process. The primary consideration is to determine the (sub)set of genes for use as the baseline for a normalization method. That is, normalization can be based on either an entire set of genes or a certain subset of genes, such as housekeeping genes that are not regarded to change the expression level under the experimental condition or some added set of control genes. Two assumptions are commonly made on normalization: (i) most genes do not change their expression level; and (ii) the total intensity across all spots in the array should be the same. The global normalization method uses all genes on the array for adjustment; it uses the mean or median as the normalization factor based on the two assumptions. For each array, the data are normalized by dividing individual gene intensity by the mean or median intensity of the array. However, the global mean/median normalization method fails to account for spatial- and intensity-dependent biases that have been observed in many experiments.

Two known statistical methods proposed for normalization are the analysis of variance (ANOVA) model^[26,27] and the scatter-plot smoother “lowess” fit.^[31] Although both procedures consider two-color fluorescence array, they can be applied to one-color data with modifications. The ANOVA procedure^[27] recommends modeling the logs of individual red and green intensities. The ANOVA model uses mean estimates to perform global adjustments for array, dye, treatment, gene effects, and their appropriate interactions simultaneously. However, as in the case of global normalization, the ANOVA method is a constant adjustment, with respect to specific effects such as dye biases. Alternatively, the lowess fit^[31] uses local regression to account for intensity- and spatial-dependent dye biases. The lowess fit is a scatter-plot smoother that performs

robust locally linear fits. Yang et al.^[31] recommended performing an array-by-array normalization on the log-ratios instead of the log-ratio of two intensities. Unlike the ANOVA approach, this lowess approach fits different lowess curves for different arrays. These two procedures can be formulated by a generalized additive model.^[32]

In a recent study, in order to minimize the non-concordance of inter-laboratory measurement of Affymetrix GeneChip™ results, Lee et al.^[33] demonstrated that labeling extension values (LEVs), which are correlation coefficients between probe intensities and probe positions, are significantly correlated with the gene expression levels on eukaryotic Affymetrix microarray data. LEVs have proven to be useful in exploring laboratory signatures, which represent the systemic variations uniquely produced in each laboratory during the microarray procedures from probe labeling and hybridization, to signal detection. Lee et al.^[33] Treated LEVs can be used as a filtering parameter for improving inter- and intra-laboratory comparability of gene expression profiles without compromising subsequent functional analyses of biological networks on them.

IDENTIFYING DIFFERENTIALLY EXPRESSED GENES AND GENE SET ANALYSIS

A microarray experiment is conducted to study the changes in gene expressions under different experimental conditions of interest. The simplest microarray experiment is performed to identify a subset of genes that are differentially expressed between control and treated groups, for example, between drug treatment and no drug treatment. The fold-change has been used as a criterion to identify differentially expressed genes in early microarray studies as the number of replicates was small or none. In the fold-change approach, a gene is said to be differentially expressed if the ratio in absolute value of the expression levels between the two conditions exceeds a certain threshold, for example, two-fold or three-fold change. The fold-change has been known to be a poor choice for identifying differentially expressed genes.^[34,35]

Identifying Differentially Expressed Genes (Gene Selection)

Identification of differentially expressed genes can be separated into two steps.^[34] The first step is to calculate a discriminatory score that will rank the genes in order of evidence of differential expressions. The second step is to determine a threshold cutoff from the ranked scores to select the differentially expressed genes.

Gene Ranking

The data are typically transformed in log₂ scale after normalization. Differential expression can be evaluated by

comparing the difference between the mean expressions of the two conditions. The difference, denoted by M , represents the fold-change between two samples. Because of a wide range of magnitudes and variability among different genes in the array, the fold-changes computed for different genes are not directly comparable as measures of evidence of differential expressions. The M statistic can be standardized by dividing a scale parameter s (e.g., standard deviation), denoted by $T = M/s$. The T statistic has the general expression that represents the test statistics for two sample comparisons. The T statistic includes the fold-change M statistic as special case by setting $s = 1$; and T becomes Student's t -statistic when s is the sample standard deviation of the mean difference. Various T statistic variants have been proposed in microarray data analysis.^[36–44] Tusher et al.^[36] proposed the SAM (<http://www-stat.stanford.edu/~tibs/SAM/>) statistic $M/(s_0 + s)$ by adding a penalty s_0 to the sample standard deviation in the denominator to account for a very small standard deviation which results in a large t -value, where s_0 is computed from the data. When the sample size is small, the variance estimate s^2 may be imprecise. To improve the reliability of variance estimates, a number of shrinkage estimators have been proposed.^[41–44] The variance of a shrinkage estimator has the general form: $s = ws_1^2 + (1 - w)s^2$ where s_1^2 is a variance of M based on all genes in the arrays and $0 \leq w \leq 1$ is a weight depending on the sample size. These methods seem to work well and they are particularly useful when the sample size is small.

Assigning a Significance Level

The T statistic is a measure for gene ranking, but it does not provide a criterion to determine a cutoff. Statistical significance testing is designed to provide a cutoff by computing the p -value from a statistic. The p -value of a test statistic is computed either from the distribution of the test statistic or from a re-sampling method. Generally, the distribution of the normalized intensities is not normal. The permutation tests provide an alternative method to determine the significance, particularly for the test statistics that do not have a closed mathematical expression, such as SAM or shrinkage statistics; their probabilities cannot be computed directly. The principle of the permutation test is conceptually straightforward. It first computes the empirical value of the test statistic for the observed data, and then performs all possible permutations under the null hypothesis and computes the test statistic for each permutation. The p -value of the test is calculated by summing the probability of the observed outcome and the probabilities of all outcomes with the test statistic values greater than the observed value. Permutation tests do not require assumption on the distributions; they are easy to perform using high-speed personal computers or workstations. However, the test is not feasible when the number of replicates is fewer than six.^[40]

A p -value cutoff divides the genes into two sets. Ideally, the selected set would contain the differentially expressed genes and the non-selected set would contain the non-differentially expressed genes. However, the selected gene set will have false positives; likewise, the non-selected genes will have false negatives. The false-positive probability or p -value is computed under testing a single gene. Since hundreds or thousand of genes are tested, determining a cutoff should be considered in terms of an overall false-positive error. This issue is referred to as multiple hypotheses testing or testing multiple endpoints. The familywise error (FWE)^[45–47] measure is commonly used in testing multiple endpoints when the number of tests is small. The FWE approach could present a problem in the analysis since the analysis tends to screen out all but a handful of genes that show extreme differential expression if m , the total number of genes, is large. With a large number of genes involved in the comparisons, the false discovery rate (FDR) error measure^[48–50] is a more useful approach for determining a significance cutoff. The FDR error measure considers the *expected proportion of false positives among the selected genes*.^[48] Essentially, FDR considers the probability of false selections among those selected genes. The FDR approach allows the findings to be made, provided that the investigator is willing to accept a small fraction of false-positive findings.

In the FDR approach, the genes are ranked according to the p -values:

$$p_{(1)} \leq \dots \leq p_{(r)} \leq \dots \leq p_{(m)}.$$

The notation $p_{(i)}$ represents the i -th ordered p -value, and m is the number of genes in the analysis. For example, $p_{(1)}$ is the smallest, $p_{(2)}$ is the second smallest, and so on. For the desired FDR level, an FDR-controlled procedure^[51] is to find the largest $p_{(r)}$ such that $(m \cdot p_{(r)})/r \leq \text{FDR}$. Those r genes with p -values less than or equal to $p_{(r)}$ are selected as differentially expressed genes. Conversely, if r genes are selected, then an empirical FDR estimate is $(m \cdot p_{(r)})/r$.^[50] If the number of true null hypotheses, m_0 , were known, an improved FDR estimate, $(m_0 \cdot p_{(r)})/r$, could be used. Since m_0 is not typically known, m is used in practice to ensure proper control of error rates. Several statistical methods for estimation of the number of true null hypotheses have been considered by Hsueh et al.^[52] which could be used to gain additional rejections.

Both the FDR and FWE approaches emphasize controlling the false-positive error. Because of a large number of genes and an effort to maintain a low significance level, an FDR approach often results in a short list of significant genes. Some genes that have good prediction powers might not be captured in the list. In these genomic/genetic applications, both the false-positive error and false-negative error are of concern. Delongchamp et al.^[53] proposed a ROC (receiver operating characteristic) approach to determining an optimal cutoff based on minimizing the total

cost from making false-positive and false-negative errors. This approach requires estimates of m_0 and m_1 . Chen et al.^[34] illustrated an application of the ROC approach to determining a p -value cutoff.

Gene selection in many applications often targets a limited number of candidate differentially expressed genes for confirmation and further study. The differentially expressed genes so selected are referred to as statistically significant. However, if an observed change is small with a very small standard deviation, then the change can be identified as statistically significant even if it may not be significant “biologically.” In a two sample comparison, it is common to use the p -value to decide a cutoff and then focus on the genes that pass the cutoff with a higher fold-change comparison. This analysis can be plotted by the so-called volcano plot.^[34] The approach of using the p -value cutoff as the primary criterion followed by the fold-change, provides the control of false-positive error and, in the meantime, preserves the desired biological significance.

The T and T variant statistics described are for two experimental conditions; many microarray experiments involve multiple experimental conditions. The different experimental conditions can be dose levels, time points, or treatment combinations. Comparisons among several treatments or factorial designs are analyzed in linear model framework. Kerr et al.^[27] proposed a single ANOVA model for an entire microarray experiment. Jin et al.^[54] fitted separate ANOVA models for each gene. Tsai et al.^[32] proposed a generalized ANOVA model and performed the analysis for each gene. The p -value of the test statistics can be computed using the permutation method.

A microarray experiment can generate different gene lists by different filters, normalizations, analysis methods, or study objectives. In some studies, it may be of interest to select a subset of genes from the multiple gene lists. Consider a mouse experiment to study differences in gene expression among the three p53 genotypes: wild-type (+/+), knock-out (-/-), and heterozygous (+/-). A statistical analysis typically consists of a comparison among the three genotypes. An important follow-up analysis is the comparisons between the knock-out and wild-type mouse and between the heterozygous and wild-type mouse. The Dunnett's test is frequently used to generate the differentially expressed gene lists for the two comparisons. Often, it is also of interest to determine the genes that show differences in both comparisons. Chen et al.^[55] recently proposed layer ranking algorithms to provide a single preference gene list from multiple gene lists generated by different ranking criteria.

Gene Set (Enrichment) Analysis

Gene set analysis (GSA) is a statistical approach to determine whether a functionally related set of genes is expressed differently (enrichment and/or deletion) under different experimental conditions. A gene set refers to a group of genes with related functions based on biologically

relevant information, such as a metabolic pathway, protein complex, or GO (gene ontology) category.

The commonly used approach to GSA is first to identify a list of genes that are expressed differently between two experimental conditions using a statistical significance testing described above. After selecting a list of differentially expressed genes, the list is then compared to biologically pre-defined gene sets to determine whether any sets are over-represented in the list of differentially expressed genes compared to the pre-defined gene sets.^[56–58] This process of comparing the number of genes in the differential expression list with the number in a predefined gene set is known as over-representation analysis (ORA). The Fisher's exact test is typically used to assess the significance for an over-representation.^[56] The ORA approach has several shortcomings.^[59,60]

Mootha et al.^[61] and Subramanian et al.^[62] proposed Gene Set Enrichment Analysis (GSEA) to identify a significantly different gene set between the diabetic samples and normal muscles for which the ORA failed to identify any single gene set. The key concept is that the individual genes in a gene set are closely related and often have similar expression patterns. By borrowing strength across the gene set, GSA will increase statistical power. The GSA approach essentially shifts the level of analysis of the microarray experiment from single genes to sets of related genes. The work of Mootha et al.^[61] has inspired the development of various GSA methods for alternatives to the ORA approach.

In GSA, the null hypothesis is all the genes in the gene set are not associated with the experimental conditions. The alternative hypothesis can be either a one-sided or two-sided test. The one-sided test means that gene expression changes in the gene set are in one direction: either all up or all down. The basic idea in this analysis is that the gene sets are closely related and, hence, will have similar expression patterns, either up or down. The two-sided test means that the gene class can exhibit both increased and decreased gene expression.^[60]

There are many one-sided GSA statistics.^[59–63] But, most GSA statistics are for two-sided tests.^[64–67] A typical GSA approach can be summarized as follows: (i) all genes are ranked by computing a test statistic (or p -value) that measures the association between the expressions and the treatment conditions; (ii) for each gene class or functional category, a class score is calculated as a summary measure of the class; (iii) resampling methods are used to generate the null distribution of the class score for each gene class; and (iv) statistical significance is assessed by comparing the observed functional score to the percentile of the null distribution of the gene class. By considering the distribution of the entire set of genes, this approach is more powerful and interpretable. The success of a gene class testing requires development of multivariate statistics and computational algorithms for testing hundreds of variables, and a well-characterized gene class mapped to microarray probes.

CLASSIFICATION AND PREDICTION

Class prediction aims at developing a prediction model that accurately predicts the class membership of a new sample from the available gene expression data set. The prediction models can be used to discriminate between different biologic phenotypes or to predict the diagnostic category, prognostic stage, or treatment response of a patient. Development of a prediction model involves two components: (i) model building and (ii) performance assessment. Typically, the data are divided into a training set and a test set; the prediction model is developed on the training set and then is used to classify samples in the test set to assess its predictive accuracy.

Model Building

The model building step can be summarized into four components: (i) selecting feature predictors; (ii) selecting a classification algorithm; (iii) specifying the training parameters of the prediction model; and (iv) fitting the prediction model to the training samples.

Because of the large number of predictors involved, many predictors are often noisy in nature and irrelevant for prediction. The use of all predictors to build the prediction model can suppress or reduce the performance of a classifier. Selection of a subset of the most informative predictor variables, called feature selection, is commonly addressed in the development of classification algorithms.^[68,69] Feature selection is the most important task in the model building step with high dimensional data. Depending on classification algorithms, there are two general approaches to feature selection: filters and wrappers. The filter approach removes irrelevant predictors according to some pre-determined criterion such as a *p*-value. Classical classification algorithms, such as Fisher's linear discriminant analysis and *k*-nearest neighbor, often use the filter approach to select relevant predictors prior to classification.^[70–73] The filter approach is a stand-alone prior step, regardless of which classification algorithm will be used. The affects of the selected predictors on the performance of the algorithm are not taken into account. The wrapper approach finds a subset of predictors and evaluates its relevance while building the prediction model. The classification algorithms, such as stepwise logistic regression, classification trees,^[74] and support vector machines with recursive feature elimination,^[75] use the wrapper approach.

The second task in the model building is the selection of a classification algorithm. A prediction model is a mathematical function constructed on the training samples from the selected classification algorithm. Numerous classification algorithms have been proposed for applications to microarray data. Several authors have compared various classification algorithms including several variants of linear discriminant analysis, nearest neighbor classification,

logistic regression trees, partial least square analysis, neural network algorithms, naïve Bayes algorithms, shrunken centroids, several variants of classification trees, regression trees, and support vector machines.^[76–78] After selecting the algorithm, the prediction model needs to be specified before model fitting. Model specification means specifying all aspects of the model including feature selection criteria, specific functional form of the prediction model, approach and criterion for performance assessment, and so forth. For example, in many classification algorithms, a cut-point to translate a quantitative predictive index into a class label must be specified. For example, the logistic regression typically uses 0.5 as a cut-point to separate two classes based on an equal misclassification cost. After selecting the prediction algorithm to be used, the prediction model is fitted to the training data set. The objective is to search for a prediction function that optimizes the class separation. In model fitting, the parameters of the prediction model are estimated to minimize the probability of misclassification error when equal misclassification costs are assumed.

Performance Assessment

In the development of a prediction model, the most important question is the ability of the model to predict a future sample. To ensure an unbiased assessment of accuracy, the prediction model is developed in one data set and then applied to another data set to estimate the predictive accuracy. The most straightforward method of estimating the accuracy is the split-sample validation in which one portion of the data is held out (test data set) while the classifier is being developed on the remaining data (training data set) and then is tested on the test data set. In practice, data often are insufficient to split into a training set and a test set for validation. Instead, cross-validation is used to evaluate the performance of a prediction model.

Cross-validation involves repeatedly splitting the data into a training set containing most of the samples and applying the prediction rule to the test set made up of the remaining samples. The prediction accuracy estimate is the average accuracy of the numerous training-test partitions.

In cross-validation, the test data must be completely independent of the training data from which the prediction model is built. The cross-validation needs to repeat all steps of model development, including gene selection and model construction within each stage. In using the filter approach, gene selection must be conducted in the training set to avoid selection bias.^[79,80] The cross-validation estimate is, presumably, the expected accuracy of the developed classifier to predict future samples using the whole data set. Since cross-validation only uses a fraction of samples, its estimates may depend on the number of folds used. As discussed, the accuracy estimate from the leave-one-out cross-validation may be expected to be higher than the estimate from the two-fold cross-validation; also, the

leave-one-out estimate may better reflect the accuracy rate estimated from the whole data set since it uses almost the entire data set in training the classifier.

CLUSTER ANALYSIS AND PATTERN RECOGNITION

One important goal in the analysis of gene expression data is to determine the relationships between genes or gene clusters for identifying biological functions or predicting specific biological outcomes (or diseases) from the analysis of expression patterns. Clustering and visualization methods have been developed and applied to organizing gene expression data by grouping genes with similar patterns of expression. Usually, genes with previously unknown functions are simply annotated with functions of the known genes in the same cluster because they share similar expression profiles across different experimental conditions. Genes expressed with similar patterns may be coregulated by common upstream regulatory motifs or may belong to the same biochemical pathways. A cluster of unknown genes with homogeneous expression profiles may indicate the discovery of a novel function group.

Before any clustering and visualization procedures can be applied to the gene expression matrix, careful extraction of array images and appropriate normalization of system variations are necessary. A screening (data filtering) procedure is often applied in selecting a subset of genes that satisfy certain criteria of expression patterns across all arrays (treatments) for further statistical analyses. A commonly used criterion is to include genes with the expression $|\log_2 \text{Trt/Ref}| \geq 1$ in at least some experimental conditions. Minimum variation (standard deviation or range) criteria are also frequently applied. The screening process is needed for reducing the number of genes from tens of thousands to thousands or hundreds for clearer visualization, faster computation, and better interpretation. In addition to array normalization and centering, individual gene normalization is often used to scale the relative magnitude of a gene's expression profile (vector) to one. Gene normalization does not only prevent clustering procedures from being dominated by genes with extreme expression patterns; they also prevent visualizations from losing color resolution.

In this section, a gene expression time course data set from a serum stimulation of primary human fibroblasts^[81] is adopted to illustrate concepts of statistical visualization and clustering tools in gene expression analyses. The experiment used cDNA arrays with 9,800 spots, representing approximately 8,600 distinct human transcripts. Briefly, fibroblasts were grown in culture and sera-deprived for 48 hours. Serum was added back and samples were taken during various periods: at the start (designated as 0), 15 minutes, 30 minutes, 1 hour, 2 hours, 3 hours, 4 hours, 8 hours, 12 hours, 16 hours, 20 hours, and 24 hours (with one array for each of these 12 samples). Genes were selected

for their analysis if the expression level deviated from time 0 by at least a factor of 3.0 in at least two time points. The selection resulted in a gene expression matrix of size 517 (genes) $\times$ 12 (arrays). A further randomly selected subset of 100 genes is used in the illustration.

Gene Expression Matrix Map with Hierarchical Clustering

The most frequently used visualization tool for gene expression profiles is the gene expression matrix map. There are many synonyms for gene expression matrix map in the literature. Wen et al.^[81] made one of the earliest applications of matrix map to gene expression data, and Eisen et al.^[82] laid down the fundamentals of cluster analysis of gene expression patterns with matrix map. The numerical data matrix of gene expression intensities (single-color experiment) or log ratios (two-color experiment) is projected through properly chosen single directional (single-color) gray spectrum or bi-directional (two-color) gray scales. Fig. 3a is the log ratio (base 2) gene expression matrix with the 100 randomly selected genes on 12 time course arrays. A green-black-red spectrum is used to represent negative-zero-positive log ratio values with brighter (darker) colors representing extreme (mild) differentially expressed gene-array combinations. The 100 row color strips represent 100 gene expression profiles that are randomly permuted, while the order of 12 column strips representing 12 arrays remain intact to depict the time course nature of the experiments. Very little information can be visually extracted from Fig. 3a because rows (genes) are randomly permuted. It is necessary to rearrange the 100 rows to satisfy the concept of relativity^[83] such that genes with similar (different) expression profiles are placed in closer (distant) rows before any interesting pattern can be summarized from this expression matrix map.

The most commonly used permutation mechanism for rearranging row orders (gene) and column order (array) in an expression matrix map is a hierarchical clustering tree (HCT) with a binary dendrogram representing the association structure of pair-wised genes or arrays. A proximity (similarity or distance) matrix, such as a correlation matrix, is first generated. Fig. 3b is the Pearson correlation matrix of the 100 gene expression profiles with a blue-white-red bi-directional spectrum representing the negative-zero-positive correlation coefficients. A similarity proximity matrix is usually converted into a distance matrix before the dendrogram for that matrix is constructed. The second step is to identify the pair of genes with the smallest distance and to group them with a link. Distances between the newly formed group with the rest of the 98 genes are computed resulting in a new proximity matrix of size 99 $\times$ 99. The algorithm proceeds in a recursive manner to build the tree structure step by step, with one less cluster member at each step. The final tree architecture is displayed as the left panel of Fig. 3c.

Fig. 3 Gene expression matrix map with hierarchical clustering of 100 randomly selected genes from a time course data set with serum stimulation of primary human fibroblasts.^[82] (a) Gene expression matrix map for the 100 genes on 12 time points (arrays) with a green-black-red color spectrum; (b) correlation matrix map for the 100 genes with a blue-white-red color spectrum; (c) hierarchical clustering tree with sorted expression matrix map and correlation matrix map

The relative positions of terminal leaves in this tree form a linear order of the 100 genes, which is used to sort the randomly arranged input correlation matrix map into the structured matrix in the middle panel. The randomly ordered gene expression map in Fig. 3a is rearranged into the right panel of Fig. 3c. Variants of hierarchical clustering algorithms have been developed, according to the direction (agglomerative vs. divisive) of trees that are constructed and the way new distances are computed (single linkage, complete linkage, average linkage, centroid method, and Ward’s method). Sokal and Sneath^[84] describe methodologies for constructing HCTs and non-hierarchical clustering algorithms in details.

There is one possible flip associated with every intermediate node in the tree architecture. A tree with 100 genes has 99 intermediate nodes with 2^{99} possible flip combinations and 2^{99} different permutations in rearranging the gene orders. The up-regulated half (red) of the simulated

time course data in Fig. 4 is created by shifting the peaking point of a Sine curve in the directions of left-to-right and top-to-down. The down-regulated half (green) simply reverses the process. The true underlying structure of this data is a two-component model in which each component follows a smooth global trend. With different flipping mechanisms in the five panels of Fig. 4, users may observe completely different clustering patterns without seeing the global trends. When noise is added to the original smooth transitional data, as would happen with microarray data, HCT-type tree permutations would not be able to reconstruct the global transitional pattern. We see that the clustering pattern in Fig. 4e actually mimics that of Fig. 3c very well, which suggests that similar global patterns might be embedded in the fibroblast to serum gene expression data.

External and internal references can be applied to these flips, such that certain criteria may be satisfied.^[85,86] Tien et al.^[87] proposed a flipping mechanism for a conventional

Fig. 4 Flipping effects of intermediate nodes of an HCT. (a) Original simulated data with a two-smooth-component model; (b) With one node flipped; (c) With three nodes flipped; (d) With six nodes flipped; (e) With many nodes flipped

agglomerative HCT using a rank-two ellipse (R2E, an improved singular value decomposition algorithm for sorting purpose) seriation by Chen^[83] as an external reference. Using the same 100 randomly selected genes on 12 time course arrays as in Fig. 3 an average linkage HCT with random flipping of intermediate nodes is constructed in Fig. 5a. Again, the order of 12 arrays remain intact in the gene expression map (100 genes by 12 arrays) and the correlation matrix map (12 arrays by 12 arrays) to depict the time course nature of the experiments. Many gene clusters can be inferred from the gene expression matrix map and the gene-gene correlation matrix maps (100 genes by 100 genes). Fig. 5b has the gene expression and the gene-gene correlation matrix maps sorted by the rank-two elliptical (R2E) order of the 100 genes. A very smooth global trend reflecting the time-related gene expression pattern can now be explored. The R2E order in Fig. 5b is then applied to guide the flipping mechanism of Fig. 5a with the resulting HCT and sorted expression and correlation maps illustrated in Fig. 5c. While HCTs always produce permutations with good local behavior, the rank-two ellipse seriation gives the best global grouping patterns and smooth transitional trends. The resulting algorithm automatically integrates the desirable properties of each method so that users have access to a clustering and visualization environment for gene expression profiles (as well as general high-dimensional data profiles) that preserves coherent local clusters and identifies global grouping trends.

Wu et al.^[88] integrated most commonly used HCT algorithms, R2E, and several flipping methods with other visualization features into the GAP (Generalized Association Plots) package. GAP is a Java-designed exploratory data analysis (EDA) software for matrix visualization (MV) and clustering of high-dimensional data sets. It provides direct visual perception for exploring structure of a given gene

expression profile matrix and its corresponding proximity matrices for genes and arrays. Various matrix permutation algorithms and clustering methods with validation indices are implemented for extracting embedded gene expression information. GAP is more powerful and effective than conventional graphical methods when dimension reduction techniques fail or when data is of ordinal, binary, and nominal type. It can be obtained from <http://gap.stat.sinica.edu.tw/Software/GAP>.

Non-hierarchical Clustering

K-means^[89] and self-organizing maps (SOM)^[90,91] are the two most commonly used non-hierarchical clustering algorithms in gene expression pattern analysis. In the non-hierarchical clustering procedure, genes are divided into k ($k_1 \times k_2$ for SOM) partitions or groups, with each partition representing a cluster of genes. Therefore as opposed to the hierarchical clustering, the number of clusters must be known (decided) a priori.

In K-means clustering, the user first specifies k initial cluster centroids or seeds. The proximities (similarity or distance) from each gene to all k centroids are calculated. Each gene is then assigned to the closest cluster (centroid). The k new centroids are formed with new cluster members, and the genes are reallocated to one of the new k clusters. This iterative process stops if there is no reallocation of genes, or if the reassignment satisfies the criteria set by the stopping rule. Variants of K-means algorithms differ with respect to (i) the method used for obtaining initial cluster centroids or seeds; (ii) the rule used for reassigning genes; and (iii) the proximity for computing the closeness between each gene and every centroid. Because K-means method outputs only the cluster memberships for all genes, this membership information is usually displayed in colors or symbols (Fig. 6a with $k = 5$).

The SOM method combines the features of dimension reduction in multi-dimensional scaling (MDS) and pre-specified number of clusters in K-means. The goal is to represent genes in the original high-dimensional input expression space by grid points in a low-dimensional output space. Commercial packages usually limit the output space to a one-dimensional grid line or two-dimensional grid net for visualization purpose. Similar to K-means algorithm, these grid points are projected to the original high-dimensional input space as centroids for the gene expression profiles to be iteratively assigned to a cluster membership. The computation of cluster membership is confined to the grid structure in the low-dimensional output space. Final cluster membership is displayed using the output space grid structure. Gene expression profiles for genes belonging to each grid point are displayed as a multivariate statistical plot at the relative grid location. Commonly used statistical plots include parallel coordinate plot, side-by-side box-plots, and gene expression matrix map. An SOM analysis with a two-dimensional 3×3 grid and box-plots for the 100 randomly selected genes is illustrated in Fig. 6b.

Simulation studies have shown that K-mean algorithms and other non-hierarchical clustering algorithms perform poorly when random initial seeds are used. Their performance is improved when the results from hierarchical methods are used to form the initial partition.^[92] In other words, hierarchical and non-hierarchical techniques should

be applied as complementary clustering techniques rather than as competing techniques. The K-means or SOM output membership information can be used in dimension reduction plots, principal component analysis (PCA), or MDS to be discussed next.

Dimension Reduction Analysis and Visualization

There are two major statistical techniques for simultaneously visualizing thousands of gene expression profiles in a single display—dimension reduction visualization and dimension-free visualization. Because of its high-dimensional nature, dimension reduction techniques such as PCA^[93,94] and MDS^[95,96] are often applied to gene expression matrices for projecting the original high-dimensional structure onto a lower dimensional space (usually two or three) for visualizing and computational purposes. Dimension reduction visualization is often adopted for presenting gene grouping structure for methods such as K-means and SOM.

For a given gene expression matrix X of size g (genes) by a (arrays), PCA performs an eigenvalue decomposition of the $a \times a$ covariance matrix $\Sigma = X^*X/g$ as $\Sigma \mathbf{v}_k = \lambda_k \mathbf{v}_k$, where $\mathbf{v}_k$'s are the eigenvector of Σ with eigenvalue λ_k , $k = 1, \dots, a$. The PCA summarizes the dispersion of gene expression profiles as data cloud in a small number of major axes (principal components) of variation among the arrays. Alter et al.^[93] named these major axes as the eigenarrays

Fig. 6 K-means clustering and self-organizing maps (SOM) with multidimensional scaling (MDS) and principal component analysis (PCA) for the time course data set with 100 genes. (a) K-means ($k = 5$) clustering with cluster membership by symbols; (b) SOM with a 3×3 grid structure, expression profiles for genes grouped at each grid point are displayed as box-plots with cluster membership by symbols; (c) MDS with K-means membership symbols; (d) PCA with SOM membership symbols

of the original expression matrix. They normalized the arrays by filtering out the eigenarrays that were inferred to represent noise or experimental artifacts. Hastie et al.^[97] recursively applied the PCA to gene expression matrices for identifying subsets of genes with coherent expression patterns and large variation across conditions. Fig. 6d is the plot of the first two principal components of the 100 by 12 gene expression profiles with colors correspond to gene clusters identified by the SOM analysis in Fig. 6b.

Given a set of n genes (or n arrays), among which the associations are to be studied, MDS first computes proximity (distance or similarity measurement) for all pairs of objects (genes or arrays) as δ_{rs} , $1 \leq r, s \leq n$. MDS then converts the input proximities into disparities $\hat{d}_{rs}$, $1 \leq r, s \leq n$ with a transformation function f . The function f can be the identity function if proximity δ_{rs} itself is a Euclidean distance. MDS finally represents objects as points in a Euclidean space, so that the perceived distances d_{rs} between points can reflect proximities δ_{rs} between objects. For visualization purposes, the dimension of the projected space is usually kept as low as possible. Thus it is unavoidable that part of the information in the original proximity matrix of similarity (or dissimilarity) will be lost in the MDS configuration plot. Kruskal^[98] proposed a scheme for measuring how much a lower-dimensional geometrical representation falls short of a perfect match. This measure, called STandardized REsidual Sum of Squares (STRESS), is defined as
$$\text{STRESS} = \left\{ \frac{\sum_r \sum_s (d_{rs}^{(q)} - \hat{d}_{rs}^{(q)})^2}{\sum_r \sum_s (d_{rs}^{(q)})^2} \right\}^{1/2}$$
 where q (usually 2 or 3) is the dimension of the solution space. A two-dimensional MDS configuration plot using the Pearson correlation matrix of the 100 gene expression profiles is displayed in Fig. 6c, with colors corresponding to gene clusters identified by the K-means analysis in Fig. 6a. Tzeng et al.^[99] developed a new rapid metric MDS method with a low computational complexity, making metric MDS applicable for large gene expression data sets.

Many useful graphical methods for studying microarray gene expression profiles are illustrated in the *Handbook of Computational Statistics: Data Visualization* edited by Chen, Härdle, and Unwin.^[100]

Gene Network Modeling and Integrated System Biology

One of the fast growing areas of research related to gene expression data analysis is the integration of expression profiles to the existing biological databases for validating and predicting gene networks. The analysis of gene expression profiles becomes much more powerful if knowledge about other biological databases such as interaction (gene-gene, gene-protein, protein-protein) and pathways (metabolic, regulatory) can be incorporated into the modeling frameworks. DeRisi et al.^[101] used global analysis of changes in gene expression to validate known metabolic structure for

diauxic shift in yeast (*Saccharomyces cerevisiae*). Marcotte et al.^[102] proposed integrating information about gene expression, protein homologues, phylogenetic profiles, metabolic function, and experimental data into genome-wide prediction of protein functions. D'haeseleer et al.^[103] discussed applications of clustering algorithms and reverse engineering, such as Boolean networks to measure the output of the gene regulatory network from gene expression data. Jenssen et al.^[104] used pure information retrieval tools to extract biomedical knowledge from publicly available gene and text databases to create a gene-to-gene cocitation network for more than ten thousand named human genes.

CONCLUSION

DNA array experiments are novel biotechnologies that have been increasingly used in biological and medical research. The mass of data generated from a typical DNA array experiment raises numerous statistical and computational challenges in data displays and processing, experimental design, and multiple testing, cluster analysis, and prediction. There are inherent biases in microarray data due to spatial, intensity, and dye effects within an array and array-to-array variation across experimental samples. Normalization is an integral part of microarray data analysis. Design consideration for a one-color experiment is similar to the parallel design in clinical trials. For a two-color experiment, the loop design appears to be more efficient than the reference design when the number of treatments is small. When the number of treatments is large, optimal design will depend on the objectives of the experiment. Several authors have considered other design issues, such as pooling mRNA samples.^[105] The field of microarray expression analysis is booming, and new analytic methods are under development. The literature is filled with novel analysis methods. New procedures for studying gene expression are being continuously developed. Generally accepted normalization procedures and data analysis methods, based on sound statistical principles, may be possible.

Microdosing Studies

Fuyu Song

Center for Food and Drug Inspection, China Food and Drug Administration, Beijing, China

Shein-Chung Chow

Duke University School of Medicine, Durham, North Carolina, U.S.A.

Abstract

In recent years, microdosing approach has received much attention in pharmaceutical research and development. The concept of microdosing approach focuses on safety signal detection, which is primary for exploratory purpose (FDA, 2006; ICH, 2009). Burt (2011) indicated that the use of microdosing approach has great potential in shortening the development by making critical go/no-go decision early. In addition, it is believed that microdosing approach will increase the probability of success based on a limited number of subjects available. In practice, however, many scientific factors regarding the design and analysis of microdose studies are commonly encountered, which have limited the potential use of microdosing approach in pharmaceutical development. These scientific factors and/or issues include, but are not limited to, (i) distinction between microdose effect and placebo effect, (ii) microdose versus therapeutic dose, (iii) characterization of dose–response curve, (iv) accuracy and reliability of predictive model, and (v) possible false positive and false negative rates. These issues are discussed. In addition, a predictive index is proposed to assess the accuracy and reliability of predictive model established based on data collected from a microdose study.

Keywords: False positive/negative; Microdose; Placebo effect; Predictive index; Therapeutic dose.

INTRODUCTION

In pharmaceutical development, a microdose is defined as a dose that is less than 1/100th of the dose of a test substance calculated (based on animal data) to yield a pharmacologic effect of the test substance with a maximum dose of $\leq 100 \mu\text{g}$.^[1,2] Due to differences in molecular weights compared to synthetic drugs, the maximum dose for protein products is ≤ 30 nanomoles. Microdosing studies are often designed not only to evaluate pharmacokinetics or imaging of specific targets but also to induce pharmacologic effects. In practice, the harm or risk of microdose to human subjects is considered very limited and not notable, while information adequate to support the initiation of such limited human studies can be derived from limited nonclinical safety studies. In the last decade, microdose is often compared with those observed at a therapeutic dose (see, e.g., the works of Lappin,^[3] Burt,^[4] Burt et al.,^[5] and Chow and Song^[6]). As indicated by Lappin,^[3] about 80% of the microdose pharmacokinetics available in the public domain has been shown to scale to those observed at a therapeutic dose, within a twofold difference. As a result, microdosing approach is now being extended into drug (pharmacokinetics) development in situations where the concentration of a drug in cell or tissue types is relevant to its efficacy. In addition, the concept of microdosing approach has been applied to address drug–drug

interactions by giving human volunteers a microdose of the candidate drug before and after the administration of a drug known to inhibit or induce certain enzymes.^[3]

As indicated in the 2006 FDA guidance on *exploratory Investigational New Drug (IND)*, a typical microdosing study involves very limited human exposure and has no therapeutic or diagnostic intent (see also the FDA guideline^[7]).^[1] A microdosing study is considered an exploratory study that focuses on the detection of safety signals. Thus, it is suggested that preclinical and clinical approaches, as well as chemistry, manufacturing, and controls (CMC) information, should be considered when planning exploratory studies in humans, including studies of closely related drugs or therapeutic biological products. The FDA currently accepts the use of extended single-dose toxicity studies in animals to support single-dose studies in humans. For microdosing studies, a single mammalian species (both sexes) can be used if justified by in vitro metabolism data and by comparative data on in vitro pharmacodynamics effects. The route of exposure in animals should be by the intended clinical route. In these studies, animals should be observed for 14 days post-dosing with an interim necropsy, typically on day 2, and endpoints evaluated should include body weights. Because microdosing studies involve only single exposures to microgram quantities of test materials and such exposures are comparable to routine environmental exposures, routine generic

toxicology testing is not needed. For similar reasons, safety pharmacology studies are also not recommended.

The concept of microdosing approach in pharmaceutical development is encouraging. As indicated by Burt,^[4] the use of human microdosing approach in pharmaceutical development has the following benefits: (1) it takes just 6 months from laboratory bench to completion of clinical studies, (2) efficient lead candidate selection, (3) reduces expensive late-stage attrition (i.e., kill ineffective compound early and cheap), (4) substantially reduced preclinical toxicology package compared to phase I, (5) only gram quantities of non-good manufacturing practice (GMP) drug (typically 10 g) are needed, (6) any route of administration possible, including intravenous (IV), (7) absolute oral bioavailability calculation, (8) drugs can be tested in sensitive populations; renal impaired patients, women of child bearing age, and cancer patients, and (9) reduces the use of animals in research. However, Chow and Song^[6] pointed out that there are statistical issues/concerns regarding the validity of the human microdosing approach in pharmaceutical development. These statistical issues include (1) the selection of microdose (e.g., “how to distinguish the effects due to microdose and the placebo effect?” and “how to select the initial dose and the dose range under study?”), (2) the selection of study endpoint (e.g., “should a clinical endpoint or a surrogate endpoint or a biomarker be used?” and “whether the surrogate or biomarker is predictive of clinical endpoint?”), (3) the determination of sample size (e.g., precision analysis or power analysis), and (4) model selection and validation (e.g., “how to handle inter- and intra-subject variabilities?” and “how to determine the impact of nonlinearity for the dose

range under study?”). In addition, it is a concern that the extrapolation based on the results from microdose to regular dose may not be reliable because the variability associated with the dose is usually proportional to the dose.

In Section “Regulatory Perspectives,” regulatory perspectives^[1,2] regarding the use of microdosing approach in drug development are discussed followed by some scientific factors^[6] that are commonly encountered when applying microdosing approach in drug development. In Section “Prediction of Microdose,” under certain assumptions, a predictive index for comparing the microdose and a therapeutic dose proposed by Chow and Song^[6] is discussed. Some concluding remarks are given in the last section.

REGULATORY PERSPECTIVES

ICH Guideline

In 2009, the International Conference on Harmonization (ICH) published a guideline that provides international standards for the nonclinical safety studies recommended to support human clinical trials for pharmaceuticals.^[2] This guidance further suggests reducing the use of animals and other resources for drug development by considering alternative methods for safety evaluation. These methods such as microdosing approach can be used to replace current standard methods. The ICH M3 (R2) guideline recommends two different microdosing approaches, which are briefly described next (see also Table 1).

The first approach would involve no more than a total dose of 100 μ g that can be administered as a single dose

Table 1 Recommended nonlinear studies to support exploratory clinical trials

Dose to be administered	Clinical		Nonclinical	
	Start and maximum doses	Pharmacology	General toxicity studies	Genotoxicity/other
Approach 1: Total dose $\leq 100 \mu$ g (no interdose interval limitations) AND total dose $\leq 1/100$ th no-observed-adverse-effect-level (NOAEL) and $\leq 1/100$ th pharmacologically active dose (scaled on mg/kg for i.v. and mg/m ² for oral)	Maximal and starting doses can be the same but not exceed a total accumulated dose of 100 μ g.	In vitro target/receptor profiling should be conducted Appropriate characterization of primary pharmacology (mode of action and/or effects) in a pharmacodynamically relevant model should be available to support human dose selection.	Extended single-dose toxicity study in one species, usually rodent, by intended route of administration with toxicokinetic data, or via the i.v. route. A maximum dose of 1000-fold the clinical dose on a mg/kg basis for i.v. and mg/m ² for oral administration can be used.	Genotoxicity studies are not recommended, but any studies or structure–activity relationship (SAR) assessments conducted should be included in the clinical trial application. For highly radioactive agents (e.g., PET imaging agents), appropriate PK and dosimetry estimates should be submitted.

(Continued)

Table 1 Recommended nonlinear studies to support exploratory clinical trials (*Continued*)

Dose to be administered	Clinical	Nonclinical		
	Start and maximum doses	Pharmacology	General toxicity studies	Genotoxicity/other
Approach 2: Total cumulative dose $\leq 500 \mu\text{g}$, maximum of five administrations with a washout between doses (six or more actual or predicted half-lives) and each dose $\leq 100 \mu\text{g}$ AND each dose $\leq 1/100\text{th}$ of the NOAEL and $< 1/100\text{th}$ of the pharmacologically active dose	Maximal daily and starting doses can be the same, but not exceed $100 \mu\text{g}$.	In vitro target/receptor profiling should be conducted. Appropriate characterization of primary pharmacology (mode of action and/or effects) in a pharmacodynamically relevant model should be available to support human dose selection.	7-Day repeated-dose toxicity study in one species, usually rodent, by the intended route of administration with toxicokinetic data, or via the i.v. route. Hematology, clinical chemistry, necropsy, and histopathology data should be included. A maximum dose of 1000-fold the clinical dose on a mg/kg basis for i.v. and mg/m^2 for oral administration can be used.	Genotoxicity studies are not recommended, but any studies or SAR assessments conducted should be included in the clinical trial application. For highly radioactive agents (e.g., PET imaging agents), appropriate PK and dosimetry estimates should be submitted.
Approach 4: Dosing up to 14 days into the therapeutic range but not intended to evaluate clinical MTD	With toxicity in both species, follow appropriate regional guidance for clinical starting dose, if toxicity is not seen in either species (i.e., the NOAELs are the highest dose tested and doses used were not otherwise limited, e.g., not an multifunctional device [MFD]), or is seen only in one species, the clinical starting dose should be the one that gives a predicted clinical area under the curve (AUC) value (based on either interspecies PK modeling or mg/m^2 conversion) that is approximately $1/50\text{th}$ of the AUC at the NOAEL from the species yielding the lower exposure. For other considerations on initial dosing in humans, e.g., predicted PD activity, regional guidance should be consulted. Without toxicity in both species, it is recommended that the maximum clinical dose not exceed $1/10\text{th}$ the lower exposure (AUC) in either species at the highest dose tested in the animals.		2-Week repeated-dose toxicity studies in rodent and non-rodent with standard parameters assessed and where dose selection in animals is based on exposure multiples of anticipated clinical AUC at maximum dose.	Ames assay (or an appropriate alternative assay if Ames is inappropriate, e.g., for an antibacterial product) and an assay (in vitro or in vivo) capable of detecting chromosomal damage in a mammalian system.

or divided doses in any subject. This could be useful to investigate the target receptor binding or tissue distribution in a positron emission tomography (PET) study. A second use could be to assess PK with or without the use of an isotopically labeled agent. The second microdosing approach is the one that involves less than five administrations of a maximum of 100 µg per administration (a total of 500 µg per subject). This can be useful for applications similar to the first microdosing approach described above, but with less active PET ligands.

In some situations, it could be appropriate to carry out a clinical microdosing study using the IV route on a product intended for oral administration and for which an oral nonclinical toxicology package already exists. In this case, the IV microdose can be qualified by the existing oral toxicity studies as described in Table 1, Approach 3, where adequate exposure margins have been achieved. It is not recommended to investigate the IV local tolerance of the drug substance in this situation because the administered dose is very low (100 µg maximum). If a novel IV vehicle is being employed, then local tolerance of the vehicle should be assessed.

FDA Guidance

Similar to the ICH M3 (R2) guideline, in 2006, the FDA published guidance on exploratory IND study, which is intended for clinical trials that are conducted early in phase 1 such as microdosing studies. From the FDA's perspective, a microdosing study usually involves very limited human exposure, and most importantly, it has no therapeutic or diagnostic intent. As indicated by the 2006 FDA guidance, microdosing studies are often conducted prior to the traditional dose escalation, safety, and tolerance studies that ordinarily initiate a clinical drug development program. The duration of dosing in an exploratory IND study is expected to be limited (e.g., 7 days). This guidance applies to early phase 1 clinical studies of investigational new drugs and biological products that assess feasibility for further development of the drug or biological product.

In addition, the FDA published the guidance "PET Drugs—Current Good Manufacturing Practice (cGMP)," which is intended for PET drugs.^[8] The guidance addresses resources, procedures, and documentation for all PET drug production facilities. In some cases, the guidance provides practical examples of methods or procedures that PET drug production facilities can use to comply with the cGMP requirements (see also^[9]).

SCIENTIFIC FACTORS

As mentioned earlier, despite some potential benefits in the early phase of pharmaceutical/clinical development, Chow and Song^[6] pointed out that there are statistical factors regarding the validity of the human microdosing approach

in pharmaceutical development. These statistical issues and concerns are described in the sections that follow.

Microdose versus Placebo

As indicated earlier, a microdose is less than 1/100th of the dose of a test substance calculated (based on animal data) to yield a pharmacologic effect of the test substance with a maximum dose of ≤100 µg. As a result, a microdose is close to a placebo (inactive dose). Thus, an interesting question is how to distinguish whether the effect (or response) observed is due to the microdose or a placebo.

A placebo response is a simulated or otherwise medically ineffectual treatment for a disease or other medical condition intended to deceive the recipient. Sometimes, patients given a placebo treatment will have a perceived or actual improvement in a medical condition; this phenomenon is usually referred to as the placebo effect. In clinical research, placebo effects are often the subject of scientific research aiming to understand the underlying neurobiological mechanisms of action in pain relief, immunosuppression, Parkinson's disease, and depression. For example, Zubieta et al.^[10] indicated that placebos can have real, measurable effects on physiological changes in the brain detected by brain imaging techniques (see also the work of Vul et al.^[11]).

To ensure the success of microdosing studies, it is important to rule out that the observed effect is by chance alone and is due to placebo effect.

Selection of Therapeutic Dose

An effective dose is defined as the dose or amount of drug that produces a therapeutic response or desired effect in some fraction of the subjects taking it. Therapeutic dose is an effective dose that is required in order to produce a desirable (or clinically meaningful) effect. The therapeutic range of a drug is defined by the range between the minimum effective dose (MED) and the maximum tolerable dose (MTD). The MED is the lowest dose level of a drug product that provides a clinically significant response in average efficacy, which is also statistically significantly superior to the response provided by the placebo. Similarly, the MTD is the highest possible but still tolerable dose level with respect to a prespecified clinical limiting toxicity. In general, these limits refer to the average patient population. For instances in which there is a large discrepancy between the MED and the MTD, it is stated that the drug has a large therapeutic window. Conversely, if the range is relatively small, or if the MTD is less than the MED, then the pharmaceutical product will have little to no practical value.

In microdosing studies, a microdose is often compared with those observed at a therapeutic dose. The ultimate goal is to determine whether the treatment effect observed at the microdose is predictive of that at the therapeutic

dose. In practice, however, the following questions raised: (1) How to confirm that the selected therapeutic dose is truly an effective dose? and (2) Is microdose predictive of the selected therapeutic dose?

Animal Model versus Human Model

In order to establish a predictive model for human, the following predictive models are necessarily established:

1. For animal population, it is to determine that microdose is predictive of therapeutic dose.
2. Animal model is predictive of human model at a given dose. For example, at microdose, animal response is predictive of human response, while at therapeutic dose, animal response is predictive of human response.

Let A_M and A_T be the animal responses at microdose and therapeutic dose, respectively, and H_M and H_T be the human responses at microdose and therapeutic dose, respectively. In this case, suppose that we have (1) $H_T = f_1(A_T)$, (2) $A_T = f_2(A_M)$, and (3) $H_M = f_3(A_M)$ or $A_M = f_3^{-1}(H_M)$. As a result, we have $H_T = f_1 f_2 f_3^{-1}(H_M)$ or $H_T = g(H_M)$, where $g = f_1 f_2 f_3^{-1}$. It should be noted that in practice, f_1 , f_2 , and f_3 may not be linear.

Characterization of Dose–Response Curve

To determine whether the microdose is predictive of the therapeutic dose, we first need to characterize the dose–response curve based on several microdoses and perhaps a therapeutic dose or a couple of therapeutic doses. With a limited number of dose levels available, it is difficult, if not impossible, to characterize the dose–response curve. If there are only two dose levels, i.e., microdose and therapeutic dose, extrapolation may not be reliable especially when the therapeutic dose is much larger than the microdose.

In addition, the dose–response curve in a dose range under study could be either linear or nonlinear. In this case, the traditional analysis of variance (ANOVA)-type F-tests with specific contrasts (linear or nonlinear) may not be appropriate. Alternatively, Cheng et al.^[12] proposed the use of slope approach by considering slopes between dose levels to characterize the dose–response curve. The slope approach (based on either slopes between dose levels and initial dose or slopes between adjacent dose levels) was found to be effective and can describe the shape of the dose–response curve and will be able to determine whether there is a clinically meaningful difference in response between the microdose and the therapeutic dose.

Variability Associated with Dose

Heterogeneity in variance between microdose and therapeutic dose is a major concern in establishing a predictive

model based on the microdose for the therapeutic dose. At microdose, the sensitivity associated with the analytical methods then plays an important role for accurate and reliable quantitation of the response of a given microdose, which has an impact on the prediction of therapeutic dose.

In dose–response studies, it is assumed that the dose–response is a monotonic increasing function of dose. In practice, it also recognized that in a dose–response study, the variability associated with the response is often proportional to the dose. Under the monotonic assumption and the fact that variability is proportional to the dose, several statistical methods have been proposed in the literature. These methods include (1) testing for linearity or nonlinearity contrasts such as quadratic contrast in the ANOVA and (2) a slope approach proposed by Cheng et al.^[12] based on normalized responses (i.e., responses adjusted for doses).

False Negative and False Positive

In practice, an established predictive model needs to be validated. Commonly used criteria are the false negative rate and/or false positive rate, which have an impact on the accuracy and reliability of the established predictive model. The false negative rate and/or false positive rate depend(s) upon not only the study design but also assay variability and assay sensitivity. Thus, it is suggested that a pilot study be conducted for determining the false negative rate and/or false positive rate before the conduct of a microdosing study in humans.

PREDICTION OF MICRODOSE

Under certain assumptions, Chow and Song^[6] proposed a predictive index for comparing the microdose and the therapeutic dose in microdosing studies, which is described next.

Predictability Index

Let X and Y be the characteristics at a microdose from animal and human, where X and Y are independent and follow normal distributions with means μ_X and μ_Y and variances σ_X^2 and σ_Y^2 , respectively. The concept used here is that if Y is predictive of X , the probability that the ratio of the standardized responses $V = (X - \mu_X)/\sigma_X$ and $W = (Y - \mu_Y)/\sigma_Y$ is equal to 1 could be close to 1. Similar to the idea of the concept for consistency of raw materials and/or final products from two different sites,^[13] we propose the following probability as an index to assess the predictability of the two characteristics:

$$p = P\left(1 - \delta < \frac{V}{W} < \frac{1}{1 - \delta}\right), \quad (1)$$

where $0 < \delta < 1$ is defined as a limit that allows for prediction. Thus, p tends to 1 as δ tends to 1. We will refer to p

as the predictive index. A small δ implies the requirement of a high degree of consistency at the microdose between animals and humans. Under the normality assumption of X and Y , the ratio of the two centered normal variables, $U = (X - \mu_X)/(Y - \mu_Y)$, is Cauchy variable with probability density function (see the work of Cedilnik et al.^[14]):

$$f_U(u) = \frac{1}{\pi} \cdot \frac{\sigma_X/\sigma_Y}{u^2 + (\sigma_X/\sigma_Y)^2}.$$

Thus, Eq. 1 can be rewritten as

$$p = P\left((1-\delta) \cdot \frac{\sigma_X}{\sigma_Y} < \frac{V}{W} < \frac{1}{1-\delta} \cdot \frac{\sigma_X}{\sigma_Y}\right) \\ = \left[0.5 + \frac{\tan^{-1}(u)}{\pi}\right]_{u=(1-\delta) \cdot \frac{\sigma_X}{\sigma_Y}}^{u=\frac{1}{1-\delta} \cdot \frac{\sigma_X}{\sigma_Y}} \quad (2)$$

Therefore, the predictive index p is a function of the parameters $\theta = (\sigma_X^2, \sigma_Y^2)$. Suppose that observations $X_i, i = 1, \dots, n_X$ and $Y_i, i = 1, \dots, n_Y$ are collected. Thus, using the invariance principle, the maximum likelihood estimate of p can be obtained as

$$\hat{p} = \left[0.5 + \frac{\tan^{-1}(u)}{\pi}\right]_{u=(1-\delta) \cdot \frac{\hat{\sigma}_X}{\hat{\sigma}_Y}}^{u=\frac{1}{1-\delta} \cdot \frac{\hat{\sigma}_X}{\hat{\sigma}_Y}}, \quad (3)$$

where $\hat{\sigma}_X^2 = \sum_{i=1}^{n_X} (X_i - \bar{X})^2 / n_X$, $\hat{\sigma}_Y^2 = \sum_{i=1}^{n_Y} (Y_i - \bar{Y})^2 / n_Y$, and $\bar{X}$ and $\bar{Y}$ are the sample means of X and Y , respectively. In other words, $\hat{p} = h(\hat{\theta}) = h(\hat{\sigma}_X^2, \hat{\sigma}_Y^2)$. Similar to the idea of the concept for consistency of Tse et al.,^[13] it can be verified that

$$\frac{\hat{p} - p - B(\hat{p})}{C(\hat{p})} \longrightarrow N(0, 1),$$

where $B(\hat{p})$ and $C(\hat{p})$ are the expected value and standard deviation of $\hat{p}$. Under this asymptotic result, a $(1 - \alpha) \times 100\%$ confidence interval of p can be obtained. Let $LL(\hat{p})$ be the lower limit of the confidence interval. Following the similar idea of consistency proposed by Tse et al.,^[13] we propose the following quality control (QC) criterion for examination of prediction of microdose. If the probability that the lower limit $LL(\hat{p})$ of the constructed $(1 - \alpha) \times 100\%$ confidence interval of p is greater than or equal to a prespecified QC lower limit—say QC_L exceeds a prespecified number β (say $\beta = 80\%$), then we claim that U and W are consistent or similar. In other words, U and W are consistent or similar if

$$P(QC_L \leq LL(\hat{p})) \geq \beta, \quad (4)$$

where β is a prespecified constant.

Sample Size Requirement

In practice, it is necessary to select a sample size to ensure that there is a high probability, say β , of consistency between U and W when in fact U and W are consistent. It is suggested that the sample size is chosen such that there is more than 80% chance that the lower confidence limit of p is greater than or equal to the QC lower limit, i.e., $\beta = 0.8$. In other words, the sample size is determined such that $P\{QC_L \leq LL(\hat{p})\} \geq \beta$. This leads to

$$P\{QC_L \leq \hat{p} - B(\hat{p}) - z_{\alpha/2} \sqrt{\text{Var}(\hat{p})}\} \geq \beta.$$

Thus,

$$P\{QC_L + z_{\alpha/2} \sqrt{\text{Var}(\hat{p})} - p \leq \hat{p} - p - B(p)\} \geq \beta.$$

This gives

$$P\left\{\frac{QC_L - p}{\sqrt{\text{Var}(\hat{p})}} + z_{\alpha/2} \leq \frac{\hat{p} - p - B(p)}{\sqrt{\text{Var}(\hat{p})}}\right\} \geq \beta.$$

Therefore, the sample size required for achieving a probability higher than β can be obtained by solving the following equation:

$$\frac{QC_L - p}{\sqrt{\text{Var}(\hat{p})}} + z_{\alpha/2} \leq -z_{1-\beta}. \quad (5)$$

Assuming that $n_X = n_Y = n$, then the common sample size is given by

$$n \geq \frac{(z_{1-\beta} + z_{\alpha/2})^2}{(p - QC_L)^2} \left\{ \left(\frac{\partial \hat{p}}{\partial \mu_X} \right)^2 V_X + \left(\frac{\partial \hat{p}}{\partial \mu_Y} \right)^2 V_Y + \left(\frac{\partial \hat{p}}{\partial V_X} \right)^2 (2V_X^2) + \left(\frac{\partial \hat{p}}{\partial V_Y} \right)^2 (2V_Y^2) \right\}. \quad (6)$$

The above result suggests that the required sample size will depend on the choices of α , β , V_X , V_Y , $\mu_X - \mu_Y$, and $p - QC_L$.

CONCLUDING REMARKS

As indicated by Lappin^[3] and Burt,^[4] the application of microdosing approach as a tool for early drug selection and development is growing and can be applied to drug-to-drug interaction by examining drug concentrations in tissues and certain cell types. Both ICH guideline and FDA guidance, however, emphasize that microdosing approach is for exploratory purpose, and it should focus on the safety in the early phase of pharmaceutical/clinical development rather than on the development for efficacy.

In practice, many scientific factors and practical issues, which limit the possible application of microdosing approach in pharmaceutical research and development, remain unsolved. These scientific factors include, but are not limited to, (1) the issue of placebo effect both at the microdose and at the therapeutic dose, (2) the prediction of animal model to human model, (3) the selection of therapeutic dose, (4) the characterization of dose–response curve, (5) accuracy and reliability of extrapolation (prediction) of the microdose to the therapeutic dose, and (6) the assessment of false positive/negative of microdose prediction. These practical issues have limitations in many aspects on drug development for efficacy.

Although the predictive index proposed by Chow and Song^[6] can examine the closeness between the treatment effects at microdose and therapeutic dose under a simple study design, design and analysis of microdosing studies are still not fully understood. In practice, it is suggested that appropriate statistical methods should be developed under a valid design for a rigorous and more accurate and reliable assessment of the performance of microdosing approach in pharmaceutical development.

Minimization Procedure

Dongsheng Tu

NCIC Clinical Trials Group, Queen's University, Kingston, Ontario, Canada

Abstract

This entry illustrates the minimization procedure through an example and discusses its advantages and disadvantages in comparison with stratification and other procedures.

Keywords: Minimization; Randomization; Stratification.

INTRODUCTION

Randomized clinical trials are considered as “golden standard” in evaluating a new treatment or therapy. From the name, it is easy to know that the randomization is one of the most important components in a clinical trial. Randomization procedure was introduced by R.A. Fisher in the 1920s when designing experiments in agricultural studies, and it was first implemented in medical settings by A.B. Hill in the 1960s.^[1] The importance and usefulness of the randomization in clinical trials are addressed in details in several other entries. Basically, randomization prevents biased allocation of subjects to treatment groups and provides the foundation for statistical tests. A simple randomization procedure can be described as an analog to the “flipping of the coin.” A subject would receive a test treatment if the head of the coin appears, or a standard treatment or placebo if otherwise. In theory, this simple randomization procedure will ensure that the treatment groups will be balanced for all covariates including patient and disease characteristics such as age and extent of disease. However, in practice, a chance imbalance may happen with simple randomization, especially when the sample size of the trial is small. If some unbalanced covariates are strongly correlated with the study outcomes, the interpretation of the treatment comparison results might be difficult, and the credibility of the study is also often under question.

A stratified randomization (or stratification, for short) may be used to avoid potential imbalances for some important covariates. These covariates are also called the stratification factors, which have potentially strong relationships with the outcomes of the study and are identified before the study starts. Within individual strata defined by the levels of these stratification factors, the simple randomization procedure, sometimes together with the blocking technique, is used to allocate subjects into different treatment groups. Kernan et al.^[2] reviewed the advantage and disadvantage of the stratification procedure: It can ensure that

treatment groups are balanced in terms of the important covariates that are stratified and would reduce both type I and type II errors; however, because of incomplete filling of blocks within strata, it reduces to simple randomization when the number of strata is large. Therneau^[3] found that the stratification begins to fail if the total number of strata is greater than approximately $n/2$, where n is the total sample size. Hallstrom and Davis^[4] recommend that with blocked stratification, the number of strata should be less than n/K , where K is the block size. Without blocking, the number of strata should be between $n/50$ and $n/100$.

In practice, however, a large number of strata may have to be included in a clinical trial. For multicenter trials, in section 2.3.2 (titled Randomization) of the ICH guideline on Statistical Principles for Clinical Trials,^[5] it is recommended that randomization procedures should be organized centrally and the center should be a stratification factor. Stratification by center would also sometimes facilitate the process of drug supply and distribution. In this case, for a trial of moderate size with more than five participating centers, the number of strata needed would easily exceed the number that was recommended. The minimization method first proposed by Taves^[6] and Pocock and Simon^[7] would be used to deal with these seemingly conflictual demands. This method was popularized by White and Freedman^[8] to biostatistical and medical audiences. It should be noted that the minimization method is one the dynamic allocation procedures in which the allocation of treatment to a subject is influenced by the current balance of allocated treatments and by the stratum to which the subject belongs and the balance within that stratum.^[5] There have been various extensions and generalizations of minimization procedures proposed in the literature. A recent review of these extensions can be found in the paper by Rosenberger and Sverdlov.^[9] In this article, we will illustrate the procedure as originally proposed by Taves^[6] through an example and discuss its advantages and disadvantages in comparison with stratification and other procedures.

PROCEDURE AND ALGORITHM

As mentioned before, the minimization procedure is a method that controls for imbalance within stratification factors in the patients assigned to the different treatment groups. It balances the marginal treatment totals for each level of a stratification factor. The basic idea of this procedure is to assign the next patient to the treatment arm with the smallest sum of marginal total of his/her corresponding level of each stratification factor. If the totals are equal, the treatment will be randomly assigned using the simple randomization method. We use a clinical trial in patients with advanced breast conducted by the NCIC Clinical Trials Group (NCIC CTG MA.19) to illustrate the algorithm for this procedure.^[10]

MA.19 was designed to randomize 350 patients with metastatic and/or recurrent breast cancer equally to receive two different chemotherapies (Arm A: DDPE + DOX and Arm B: DOX only). The study was stopped earlier than planned after 305 patients were accrued. There were four stratification factors identified before the study was opened: (i) whether the patient received prior cytotoxic treatment (yes, no); (ii) whether the patient was registered to MA.16, another NCIC CTG study (yes, no); (iii) whether the patient had visceral disease (yes, no); and (iv) the center the patient was treated (there were 40 centers at initiation of the trial and more would be added during the process of the trial).

In general, suppose that there are a total of M stratification factors and each has h_i levels, where $i = 1, 2, \dots, M$. For MA.19, assume that $i = 1$ for the factor of prior cytotoxic treatment; $i = 2$ for the factor of registration to MA.16; $i = 3$ for the factor of presence of visceral disease; and $i = 4$ for the factor of the center. Then $h_1 = h_2 = h_3 = 2$ and $h_4 = 40$. Define, at any time of the accrual period, $n(m(i), i, k)$ as the total number of patients who were in the $m(i)$ th level of the i th stratification factor and were allocated to receive the k th treatment, where $m(i) = 1, 2, \dots, h_i$ for $i = 1, 2, \dots, M$ and $k = 1$ or 2 ($k = 1$ means the patient was allocated to arm A; $k = 2$ means the patient was allocated to arm B). For example, in MA.19, assume that for $1 \leq i \leq 3$, $m(i) = 1$ if the level is “yes” and $m(i) = 2$ if the level is “no,” and for $i = 4$, $m(i)$ is the number of the center (labeled from 1–40). Then if $i = 2$, $m(2) = 1$, and $k = 2$, $n(m(2), 2, 2)$ is the total number of patients who had registered to MA.16 and had been allocated to treatment arm B.

The patient allocation process in minimization procedure starts with assigning the first patient to a treatment determined by the simple randomization procedure such as “flipping of a coin.” Then at any future time when a new patient arrives, his/her values of each stratification factor are recorded. Suppose that a new patient arrives with $m(i)$ as the value for the level of the stratification factor i . Then we calculate for each treatment k , $T(k) = \sum_{i=1}^M n(m(i), i, k)$ the sum of the total number of patients with value $m(i)$ for the i th stratification factor, where $i = 1, 2, \dots, M$, and

allocated to treatment k (a given patient may be counted multiple times). The following example illustrates the calculations of $T(k)$. Suppose that a new patient to be allocated had prior cytotoxic treatment ($m(i) = 1$ for $i = 1$), was not registered to MA.16 ($m(i) = 2$ for $i = 2$), was presented with visceral disease ($m(i) = 1$ for $i = 3$), and was from center #12 ($m(i) = 12$ for $i = 4$), the following are the number of patients allocated into each treatment arm just before this patient has arrived:

	Arm A	Arm B
$m(1) = 1$	$n(m(1), 1, 1) = 12$	$n(m(1), 1, 2) = 8$
$m(2) = 2$	$n(m(2), 2, 1) = 11$	$n(m(2), 2, 2) = 12$
$m(3) = 1$	$n(m(3), 3, 1) = 4$	$n(m(3), 3, 2) = 3$
$m(4) = 12$	$n(m(4), 4, 1) = 4$	$n(m(4), 4, 2) = 6$

From the above table, we can immediately get $T(1) = 12 + 11 + 4 + 4 = 31$ and $T(2) = 8 + 12 + 3 + 6 = 29$.

After the calculations of $T(1)$ and $T(2)$, based on the minimization principle, the new patient will be assigned to the treatment group with lower $T(i)$. In the last example, the new patient would be assigned to treatment arm B. If $T(1) = T(2)$, the treatment for the new patient will be assigned using a simple randomization procedure. This process is repeated whenever there is a patient waiting for allocation.

We can also illustrate the details of above process using a small trial with ten patients and one single stratification factor, which is the gender of the patient and has two levels (male vs. female).

Assume the first patient is a male. Because he is the first patient who enters the study, we have to allocate treatment to him using a simple randomization procedure. Assume the outcome from this simple procedure is treatment 1. Now assume the second patient to be allocated is a female. As no female patient has been randomized before, we have $T(1) = T(2) = 0$. Therefore, we also have to allocate this patient using the simple randomization procedure. Assume the outcome is treatment 1 again. If the third patient to be allocated is a female again, she will be allocated to treatment 2 because one female patient has been previously allocated to treatment 1 and no female patient to treatment 2 (i.e., $T(1) = 1$ and $T(2) = 0$). Now assume the fourth new patient is a male. He will also be allocated to treatment 2 because $T(1) = 1$ and $T(2) = 0$. If the fifth new patient is a male again, he will have to be assigned a treatment by the simple randomization procedure because each treatment group has one male patient, which leads to $T(1) = T(2) = 1$. Let the outcome be treatment 1. Now assume the next patient is a female, we will also have to allocate her by the simple randomization procedure since we also have $T(1) = T(2) = 1$. Assume the outcome is treatment 2 and next patient is a male. Because two male patients have now been allocated to treatment 1 and one to treatment 2 (i.e., $T(1) = 2$ and $T(2) = 1$), this patient will be allocated

to treatment 2. If the next patient is a female, she will be allocated to treatment 1 because one female patient has been allocated to treatment 1 and two to treatment 2 (i.e., $T(1) = 1$ and $T(2) = 2$). Now assume last two patients are both male. We will have to assign the treatment to the first one using the simple randomization procedure because two male patients have been allocated to each of two treatments (i.e., $T(1) = T(2) = 2$). If the outcome of the simple randomization procedure is treatment 2, the last patient will be allocated to treatment 1 because now we have $T(1) = 2$ and $T(2) = 3$. At the end, three of six male patients and two of the four female patients are allocated to each of the two treatment groups.

The above process can be easily programmed using any computer language that can generate object-oriented user interfaces, such as Visual Basic, JAVA, or SAS/AF, and implemented with telephone or web-based randomization systems. The procedure can also be easily generalized in the following situations: where there are more than two treatment arms, or it is desired to allocate the patients into treatment groups with unequal probabilities.

COMPARISON WITH OTHER PROCEDURES

Many studies using the minimization procedure have demonstrated the ability of minimization to achieve balance. Table 1 the final balance achieved in the MA.19 study (center is summarized only by Canadian vs. non-Canadian), which shows an excellent balance in all the level of the stratification factors.

Pocock and Simon^[7] showed that minimization might be more effective than stratification when trials are small (<100 patients) and there are many (>3) covariates. Therneau^[3] demonstrated that minimization outperformed stratification under a wide range of plausible conditions with

respect to achieving overall balance on the distribution of stratification factors between treatment groups. He concluded that minimization can accommodate a large number of factors from 10–20 without difficulty; however, as mentioned before, stratification begins to fail if the total number of distinct combinations of factor levels (called also as strata) is greater than approximately $n/2$, where n is the total sample size. Stratification is aimed at achieving balance between treatment groups within each combination of the stratification factor levels. Minimization, however, balances only with the marginal distribution of these factors, i.e., within each level of the stratification factors.

Birkett^[11] examined the comparative effects of stratification and minimization on the type I and II errors. In a series of simulations, he found that minimization performed at least as well as stratification, but pointed out that his conclusions were limited to the condition he examined, i.e., normally distributed and independent variables. Tu et al.^[12] reported results from simulation studies which compared the impact of minimization on statistical efficiency, which are measured by the simulated type I and II errors of statistical tests for the comparisons of treatment groups formed by the following methods: (i) random allocation with blocking, (ii) stratification with blocking, and (iii) minimization. The results showed that whether minimization increases precision (i.e., reduces type I or II errors) depends the presence or the absence of interaction among the stratification factors. The minimization procedure is better than stratification, only if the interaction is not substantial, possibly because of the inability of minimization to achieve balance among all the strata. Signorini et al.^[13] recently proposed a new dynamic allocation method as an alternative to minimization. With this method, balance in each stratum can also be achieved. To use this method, the stratification factors are first divided into different levels. For example, for a trial with two stratification factors—gender and hospital—gender within hospital could be considered as level 1; hospital as level 2; and the overall trial as level 3. Define $D_i = |T_i - C_i|$ as the difference of the numbers of patients allocated to the treatment and the control groups at level i , respectively, where T_i and C_i are the numbers allocated to the treatment and the control groups at level i , respectively. Define a critical value d_i for each level. If level i is the lowest level such that $D_i \geq d_i$, force the allocation of the next patients so as to reduce D_i . If $D_i < d_i$ for all i , then randomly allocate the patient. Simulations showed that this method could achieve stratum balance. However, there are still many practical issues to be resolved, e.g., how d_i could be objectively determined.

DISCUSSION

The ICH guideline on Statistical Principles for Clinical Studies^[5] and the European Committee for Proprietary Medicinal Products (CPMP) Points to Consider

Table 1 Accrual by Stratification Factor in MA.19

	Number of patients (%)		
	DPPE/DOX	DOX	TOTAL
Total randomized	153	152	305
<i>Prior cytotoxic treatment</i>			
Yes	20 (13.1)	19 (12.5)	39 (12.8)
No	133 (86.9)	133 (87.5)	266 (87.2)
<i>Registration to MA.16</i>

document on Adjustment for Baseline Covariates^[14] discussed specifically the use of dynamic allocation procedures, of which the minimization procedure is a typical example. The ICH guideline warns that “deterministic dynamic allocation procedures should be avoided and an appropriate element of randomization should be incorporated for each treatment allocation” and CPMP document strongly discourages the use of dynamic allocation methods. The minimization procedure described above could be considered as a deterministic procedure, except in the situation when $T(1) = T(2)$, where a subject will be randomly allocated, because the values of the stratification factors for all the subjects previously allocated will determine the allocation for a new subject. For this reason, some people suggested that a simple randomization procedure be performed after $T(1)$ and $T(2)$ are calculated to decide the allocation for a new subject. In our opinion and from our experience, this may destroy the whole purpose of the minimization procedure and thereby reduces it to a simple randomization procedure. At the end, even the marginal balance may not be achieved. In order to avoid the predictability of a deterministic procedure, such as minimization, we advise that it is used only in multicenter trials where there is a central office responsible for treatment allocations. In this case, a separate system group and a sophisticated computer program will keep not only investigators in the centers but also data management personnel at the central office blind to the treatment code. Another proposal is to allocate the subject to the treatment group of lower marginal total with higher probability rather than certainty.^[7,15] However, it is still not clear what would be the best choice for this probability, which may depend on the size of the trial.^[16]

Even if the deterministic aspect of the dynamic allocation methods is avoided by the methods described above, the CPMP document still discourages the use of dynamic allocation methods because “it remains controversial whether the analysis adequately reflects the randomization scheme.”^[14] There have been claims that the analysis based on permutation tests should be used if minimization is used as the method of treatment allocation instead of asymptotic tests. Buyse^[15] has argued that “simulations show that it does not make any material difference what type of test is used.” Kalish and Begg^[17] have shown by simulations that the treatment allocation method has little, if any, effect on the size and power of the tests used to analyze the results of the trial.

Another warning in the ICH guideline is that “the complexity of the logistics and the potential impact on the analysis should be carefully evaluated when considering dynamic allocation.” Logistically, with a central randomization office, our experience shows that the minimization procedure would make it easier for the management of drug supply and distribution and for the handling of randomization and unblinding requests. Partly due to this, the minimization procedure has become a standard method

for many Cooperative Cancer Research Groups supported by the U.S. National Cancer Institute.

When a clinical trial is designed, however, whether the study will be stratified and which method will be used for the allocation of patients are usually not taken into account in the sample-size calculations. The practical reason in most of the situations is that it is impossible or difficult to estimate correctly the percentages of the patients who will be accrued into each stratum. Another reason behind this practice is that stratified tests that take into consideration of stratification are usually more powerful than those tests that ignored stratification factors. Thus, the sample size calculated without the information of strata is usually more conservative if these stratified tests will be used in the final analysis. It has also been observed that even slight imbalances in important prognostic factors might cause serious bias treatment comparisons and substantial loss of power.^[18] Therefore, it is important to identify important prognostic factors before the study and to use a method, such as minimization, that balances the treatment arms in terms of these important prognostic factors.

CONCLUSION

The minimization procedure would be an alternative to the standard stratification procedure when there are many factors to be stratified, or each factor has a large number of levels, and there is a central randomization office which performs the allocation. As for the stratified randomization, it is important to identify stratification factors that are strongly related to the study outcomes before the study starts. All the levels of stratification factors should be clearly defined, and the assessment of these factors should not contain difficult measures to avoid allocating patients to the wrong strata. The computer program that implements the minimization procedure should be carefully validated according to appropriate regulatory guidance.

Minimum Effective Dose

Keumhee Carriere Chough

Department of Mathematical and Statistical Sciences, University of Alberta, Edmonton, Alberta, Canada

Abstract

The minimum effective dose is defined as the lowest dose level of a pharmaceutical product that provides a clinically significant response in average efficacy. This entry briefly summarizes how the determination of the MED is made.

Keywords: Analysis of variance; Dose-response; Model-based approach.

INTRODUCTION

Moore¹ has pointed out that the difference between a drug and a poison is the dose. To provide an effective and safe treatment of a certain disease, it is extremely important to identify the dosing range of a pharmaceutical product. The lower bound of the dosing range is referred to as the minimum effective dose (MED). The MED is then defined as the lowest dose level of a pharmaceutical product that provides a clinically significant response in average efficacy, which is also statistically significantly superior to the response provided by the placebo.^[2–5] According to this definition, the MED must produce a response with a magnitude of clinical superiority over placebo because a small but statistically significant response resulting from either a large sample size or a small variability can be of no clinical application. On the other hand, the MED must also provide a statistically significant clinical response. This is because a large clinical response, while statistically insignificant from the placebo response produced at a dose level, cannot establish the scientific evidence of the effectiveness at that dose level. Similarly, the maximum tolerable dose (MTD) is the highest possible but still tolerable dose level with respect to a pre-specified clinical limiting toxicity.^[6,7] The therapeutic range (window) is then defined as the range of the dose levels from the MED to the MTD. If the difference between the MTD and the MED is large, then the corresponding pharmaceutical product is said to have a wide therapeutic range. On the other hand, if the MTD is very close to or even smaller than the MED, then the product is practically of little therapeutic value. The definition discussed above focuses on the average efficacy of a patient population. Fillon^[3] has defined the MED for a particular patient as the lowest dose level that provides a pre-specified clinical effectiveness above a pre-determined percentage of patients. We refer to the first traditional definition as the population minimum

effective dose (PMED) and the second definition as the individual minimum effective dose (IMED).

DESIGN AND ANALYSIS

The MED is usually estimated based on the data of primary efficacy end points collected from dose-ranging or dose-response clinical trials conducted during the Phase II clinical development of a drug product. These dose-response studies are usually randomized, double-blind, parallel-group designs comparing several doses to a concurrent placebo. Occasionally, a crossover design such as William's design^[8] is employed. Many clinicians, however, find that a variety of titration designs either with or without a concurrent parallel placebo group for dose ranging studies are useful because of the impression that they mimic the clinical practices in the real world. The ICH E4 guidance on "Dose-Response Information to Support Drug Registration"^[9] classifies the dose-response designs as follows: (i) parallel dose-response design, (ii) crossover dose-response design, (iii) forced titration design, and (iv) optional titration design (placebo-controlled titration to end points).

As pointed by the ICH E4 guidance, a randomized multiple crossover design of several doses can be employed if drug effect develops rapidly and patients return to baseline conditions quickly after termination of therapy, if responses are not irreversible (e.g., cure or death), and if patients have reasonably stable disease. The primary advantages of crossover design can be summarized as follows: (i) the estimation of dose-response curve and MED depends upon intra-subject variability and hence requires fewer patients than the parallel-group design; (ii) because each patient receives several different doses, the distribution of individual dose-response curves and IMED, as well as the population MED and average dose-response curve, may be estimated; and (iii) as compared to titration designs,

dose and time are not confounded with each other and carryover effects can be better characterized. However, on the other hand, the potential drawbacks of crossover dose-response designs are as follows: (i) there may be analytic problems, if there are too many dropouts; (ii) the duration of the study may be too long for certain patients to endure; and (iii) there is a possibility of carryover effects, baseline comparability, and treatment-by-period interaction.^[9]

It is crucial to include a concurrent placebo group to estimate the MED because a dose of any drug product cannot establish its effectiveness without the comparison with the placebo. Furthermore, the ICH E4 guidance also suggests the inclusion of one or more doses of an active drug control. The inclusion of both placebo and active concurrent control groups allows an evaluation of assay sensitivity and an assessment for detecting the difference between an ineffective drug and an ineffective study. In addition to choosing an appropriate statistical design, the selection of dose levels, the number of dose levels, and the sample sizes for each dose group are equally important for the estimation of the MED. These issues are not only related to each other but also very difficult to deal with. The dose range should be chosen as wide as possible within the safety limit so that a dose-response relationship can be adequately characterized. Although a linear relationship can be derived from the response of two active doses, the ICH E4 guidance^[9] indicates that this approximation is usually not sufficiently informative. In addition, a positive slope can still provide evidence of a drug effect even without placebo concurrent control. It cannot be used for the estimation of MED that requires a clinically significant and meaningful response which is statistically significant superiority over the placebo. Furthermore, a difference between drug groups and placebo control unequivocally shows the effectiveness of the drug. The number of dose levels, including the active agent and the placebo, therefore should be at least four. Ideally, it is preferable to select a dose level whose response is not expected to be statistically different from the placebo response so that the MED can be more accurately estimated. Sample size determination includes an estimation of the total sample size and its distribution across different dose groups. Ruberg^[4] has suggested that the sample size should be determined based on the statistical test for the hypothesis of interest for primary efficacy clinical end points. However, it should be noted that the sample size required for a dose-response study may be different from that for the estimation of MED. Further research for the sample size for the estimation of MED is needed.

Two approaches are commonly used to estimate the MED. The first approach is the method of hypotheses testing based on the analysis of variance (ANOVA). It includes step-down, step-up, and single-step procedures. The step-down procedures consist of the Dunnett's step-down procedure, Williams's test for ordered alternative,^[10] and the step-down linear contrasts.^[11,12] The Bonferroni procedure proposed by Hochberg,^[13] which was later refined by

Dunnett and Tamhane^[14] in conjunction with the application of Helmert contrasts, is a typical step-up procedure for the estimation of the MED. Ruberg^[15] introduced the use of the step contrasts and basin steps as single-step procedures to estimating the MED. The MED estimated by the method of ANOVA would be one of the dose levels evaluated in the trial. The interval estimation for the MED is not yet developed for the approach by the ANOVA. Non-parametric methods based on the Mann-Whitney statistic for the identification of MED are also available^[16,17] when the normality assumption of the primary end point is in doubt. The other approach is the model-based method. Although a functional form such as the four-parameter logistic function is generally required, both point and interval estimates can be obtained by the model-based approach.^[18] In addition, one can more directly incorporate the information of the effective response into the assumed model for the estimation of the MED. Ruberg^[4,18] has provided a comprehensive review of the design and the estimation of the MED.

CONCLUSION

The clinically meaningful response can be expressed either by the original actual response at a particular dose level or as an additional clinically meaningful improvement over the placebo response. All approaches described above assume the clinically significant response a priori as a known constant. This assumption relies on the external validity of the past history and previous experience of the disease under study. This assumption is reasonable only if the placebo response is well established by adequate, well-controlled studies and the clinical condition for the evaluation of the pharmaceutical product is well understood. On the other hand, with respect to internal validity, the clinically significant response should be determined by the response provided by the current placebo control group. Further research in this area is needed.

Mixed Effects Models

Donghui Zhang and Chunpeng Fan

Sanofi Aventis, Bridgewater, New Jersey, U.S.A.

A. Lawrence Gould

Merck Research Laboratories, Blue Bell, Pennsylvania, U.S.A.

Abstract

This entry briefly outlines linear and non-linear mixed effect models by providing background information and estimation models for each.

INTRODUCTION

Mixed effect models have been the subject of active theoretical research for about three decades. The increasing availability of software for performing the intensive calculations required to implement mixed effect model methods has made it practical to implement these methods in a wide variety of applications. One area of application for which mixed effect models have been particularly well suited is that of repeated measurement trials, in which a subject receives a treatment or a sequence of treatments repeatedly over a period of time. Typical examples of repeated measurement trials include longitudinal trials of the effect of long-term administration of a treatment and pharmacokinetic trials in which sequences of blood samples are obtained to study the time course of the concentration of a drug in the blood following one or more applications of the drug. Another area of application for mixed effect models is in accounting for excess variation attributable to intraclass correlation arising from clustering. Typical examples include members of a family, students within a class and classes within a school, patients within a center contained in a multicenter trial, etc. Mixed effect models express an observed response explicitly as a function of fixed effects such as administered treatment, gender, and age, and of random effects such as measurement error, biological variation within a subject, or population variation among subjects. Mixed effect models may be linear, when the response is expressed as the sum of fixed and random effects, or non-linear, when the response is a non-linear function of the fixed and random effects. The application of mixed effect model methods requires assumptions about the distributions of the random effects. The usual assumption is that the effects are normally distributed, although other distributional assumptions may be made depending on the application. This entry briefly outlines linear and non-linear mixed effect models. More comprehensive treatments of the issues may be found in Bryk and Raudenbush,^[1] Khuri et al.,^[2] Rao and Kleffe,^[3] Searle,^[4]

and Searle et al.,^[5] which deal primarily with linear mixed effect models; Gallant,^[6] Carroll et al.,^[7] Davidian and Giltinan,^[8] and Vonesh and Chinchilli,^[9] which address non-linear models; and Andersen^[10] and McCullagh and Nelder,^[11] McCulloch and Searle,^[12] Diggle et al.,^[13] Hardin and Hilbe,^[14] and Dobson and Barnett,^[15] which address generalized linear mixed effect model methods that are appropriate when the data are discrete, such as categories, rather than continuous. A comprehensive coverage on the linear mixed effects model, the generalized linear mixed model, and the non-linear mixed model can be found in Demidenko.^[16] Random effects can be introduced into survival-type models to account for missing covariates and clustering.^[17–34]

LINEAR MODELS

Background

Conventional general fixed effect linear models can be written as

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon} \quad (1)$$

where $\mathbf{y}$ denotes a vector of observations, $\boldsymbol{\beta}$ denotes a vector of unknown constants (parameters), $\mathbf{X}$ denotes a matrix of (known) covariates or indicator variables, and $\boldsymbol{\varepsilon}$ denotes a vector of unknown residual errors. The elements of $\boldsymbol{\varepsilon}$ are ordinarily assumed to be independently distributed with zero mean and constant variance σ^2 . Circumstances in which a more complex covariance structure for $\boldsymbol{\varepsilon}$ would be appropriate can usually be approached effectively using mixed model methods as described below. Methods for estimating the elements of $\boldsymbol{\beta}$ under a variety of assumptions about the distribution of the elements of $\boldsymbol{\varepsilon}$ are well known.^[4] Non-linear fixed effect models usually replace the $\mathbf{X}\boldsymbol{\beta}$ term in Eq. 1 with a non-linear function $f(\mathbf{X}, \boldsymbol{\beta})$ of parameters and covariates, although they can

also be formulated in other ways such as through link functions.^[11]

In applications such as the longitudinal studies, when the aim is to study the evolution of response over time, the observation vector $\mathbf{y}$ may consist of sequences of values, each sequence corresponding to a different subject or patient. At least two sources of variability arise in such cases. One source of variability corresponds to the variation among a subject's sequence of observations beyond what the fixed effects would account for. Another source of variability is the variation between the observations on different subjects, which often will be greater than the variability among the observations made on the same subject. The idea that the observations could be functions of various kinds of random effects as well as fixed effects underlies mixed effect models.

Random effects can be incorporated into linear models by generalizing Eq. model 1 slightly to express a vector of observations as

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{\delta} + \boldsymbol{\varepsilon} \quad (2)$$

The essential difference is the addition of the term $\mathbf{Z}\boldsymbol{\delta}$, where $\mathbf{Z}$ is a matrix of known covariates and $\boldsymbol{\delta}$ denotes a vector of random effects, analogous to $\boldsymbol{\varepsilon}$. Expression 2 describes a particularly simple way to incorporate the random effects. Random effects actually can be incorporated into non-linear models in a number of ways, outlined in "Non-linear Models." Ordinarily, the elements of $\boldsymbol{\varepsilon}$ are assumed independently distributed with zero mean and constant variance σ^2 , although more complex covariance structures (e.g., autoregressive) could be assumed. The elements of $\boldsymbol{\delta}$ are also assumed to have zero mean and assumed to be uncorrelated with the elements of $\boldsymbol{\varepsilon}$, but may have a complex covariance structure, with covariance matrix $\mathbf{D}$. More usually, especially in practice, $\mathbf{Z}\boldsymbol{\delta}$ is expressed as

$$\mathbf{Z}\boldsymbol{\delta} = \sum_{i=1}^q \mathbf{Z}_i \boldsymbol{\delta}_i$$

where $\boldsymbol{\delta}$ has m_i elements and covariance matrix $\sigma_i^2 \mathbf{I}_{m_i}$, where $\mathbf{I}_{m_i}$ denotes an $m_i \times m_i$ identity matrix, and the elements $\boldsymbol{\delta}_i$ and $\boldsymbol{\delta}_j$ are uncorrelated if $i \neq j$. Then the covariance matrix $\mathbf{D}$ is block-diagonal with the matrices $\sigma_i^2 \mathbf{I}_{m_i}$, $i = 1, \dots, q$ on its diagonal, and the covariance matrix of the elements of the observation vector $\mathbf{y}$ can be written as

$$\mathbf{V} = \mathbf{V}(\mathbf{y}) = \sum_{i=1}^q \sigma_i^2 \mathbf{Z}_i \mathbf{Z}_i^T + \sigma^2 \mathbf{I}_n \quad (3)$$

Estimation

The objective of the analyses of mixed effect models is inference about the fixed effects $\boldsymbol{\beta}$ and estimation of σ^2 and the distinct elements in the covariance matrix $\mathbf{D}$

(we use vector $\boldsymbol{\theta}$ to represent the variance components). This is commonly accomplished by maximizing the likelihood of the data under a set of distributional assumptions about the random effects such as multivariate normality. The computations are generally not explicit, but instead entail successively more accurate iterative approximations to the solutions of the likelihood equations or estimating equations.^[35–37] The iterative nature of the computations means that a number of numerical analysis issues need to be considered such as convergence (at all, global vs. local), dependence on starting values, potential singularity of $\mathbf{V}$, algorithm used for calculations, effect of boundaries (e.g., variance components must be positive), and computing cost. (See, e.g., Searle et al.,^[5] Chapter 8.)

Maximum Likelihood Estimation

Estimation can be carried out under the assumption of multivariate normality of the observations by the conventional maximum likelihood (ML) or by the restricted maximum likelihood (REML). Conventional maximum likelihood estimates the fixed effect parameters $\boldsymbol{\beta}$ and the variance components σ_i^2 ($i = 1, \dots, q$) as those values that maximize the logarithm of the multivariate normal likelihood

$$L = L(\boldsymbol{\beta}, \mathbf{V} | \mathbf{y}) = -\frac{1}{2} \log |\mathbf{V}| - \frac{1}{2} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta})^T \mathbf{V}^{-1} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta}) \quad (4)$$

These are usually taken as the values for which the first derivatives of L equal zero; it is necessary to verify that these values really do maximize expression 4 and that the estimates of the variance components are positive. The derivative of L with respect to $\boldsymbol{\beta}$ is

$$L_{\boldsymbol{\beta}} = \mathbf{X}^T \mathbf{V}^{-1} \mathbf{y} - \mathbf{X}^T \mathbf{V}^{-1} \mathbf{X} \boldsymbol{\beta} \quad (5)$$

and the derivative with respect to σ_i^2 , $i = 0, 1, \dots, q$, is

$$L_{\sigma_i^2} = \frac{1}{2} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta})^T \mathbf{V}^{-1} \mathbf{Z}_i \mathbf{Z}_i^T \mathbf{V}^{-1} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta}) - \text{tr}(\mathbf{V}^{-1} \mathbf{Z}_i \mathbf{Z}_i^T) \quad (6)$$

with the convention that $\sigma_0^2 = \sigma^2$ as defined in Eq. 3 and $\mathbf{Z}_0 = \mathbf{I}_n$. The estimates of the variance components derived by maximizing the log likelihood in Eq. 4 via the first derivatives provided in Eqs. 5 and 6 do not reflect the degrees of freedom involved in estimating $\boldsymbol{\beta}$.

If $\hat{\mathbf{V}} = \mathbf{V}(\hat{\boldsymbol{\theta}})$ denotes the estimated covariance matrix of the observations using the ML estimator $\boldsymbol{\theta}$ of the variance components, then the maximum likelihood estimator of $\mathbf{X}\boldsymbol{\beta}$ is

$$\text{MLE}(\mathbf{X}\hat{\boldsymbol{\beta}}) = \mathbf{X}(\mathbf{X}^T \hat{\mathbf{V}}^{-1} \mathbf{X})^{-1} \mathbf{X}^T \hat{\mathbf{V}}^{-1} \mathbf{y} \quad (7)$$

and its asymptotic covariance matrix is

$$\mathbf{V}(\text{MLE}(\mathbf{X}\hat{\boldsymbol{\beta}})) = \mathbf{X}(\mathbf{X}^T \hat{\mathbf{V}} - \mathbf{I}_X)^{-1} \mathbf{X}^T \quad (8)$$

REML Estimation

Estimates of the variance components that do reflect the degrees of freedom involved in estimating β are obtained using restricted (or residual) maximum likelihood, usually abbreviated as REML. Restricted maximum likelihood estimates of the variance components are based on the residuals after fitting the fixed effects by ordinary least squares. Thus if $\mathbf{U}^-$ denotes a generalized inverse of a matrix $\mathbf{U}$ ($\mathbf{U}^-$ is any matrix satisfying $\mathbf{U}\mathbf{U}^-\mathbf{U} = \mathbf{U}$), then $\mathbf{r} = (\mathbf{I} - \mathbf{X}(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T)\mathbf{y}$ is the vector of residuals corresponding to the observation vector $\mathbf{y}$. The expectation of $\mathbf{r}$ is zero regardless of the value of $\mathbf{V}$. The matrix $\mathbf{I} - \mathbf{X}(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T$ has $n - p$ linearly independent rows, where p is the rank of $\mathbf{X}$. Let $\mathbf{M}$ denote an $(n - p) \times n$ matrix whose rows are linearly independent vectors in the row space spanned by the rows of $\mathbf{I} - \mathbf{X}(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T$. $\mathbf{M}$ could be any $n - p$ linearly independent rows of $\mathbf{I} - \mathbf{X}(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T$. If $\mathbf{w} = \mathbf{M}\mathbf{y}$, then $\mathbf{w}$ represents an observation from a multivariate normal distribution with zero mean and nonsingular covariance matrix $\mathbf{U} = \mathbf{M}\mathbf{V}\mathbf{M}^T$. The logarithm of the likelihood under multivariate normality is

$$L = -\frac{1}{2}(\log|\mathbf{U}| + \mathbf{w}^T\mathbf{U}^{-1}\mathbf{w}) \quad (9)$$

and the derivative with respect to $\sigma_i^2, i = 1, \dots, q$, is

$$L_{\sigma_i^2} = \frac{1}{2}(\mathbf{w}^T\mathbf{U}^{-1}\mathbf{Z}_i\mathbf{Z}_i^T\mathbf{U}^{-1}\mathbf{w} - \text{tr}(\mathbf{U}^{-1}\mathbf{Z}_i\mathbf{Z}_i^T)) \quad (10)$$

The variance components can be estimated from these expressions with attention to the same computational considerations, namely, that the estimates really do maximize expression 9 and the estimates are positive (or at least nonnegative).

Estimates of the fixed effects and the asymptotic covariance matrix of the estimates are given by Eqs. 7 and 8, with $\hat{\mathbf{V}}$ calculated using the REML estimates of the variance components.

Other Estimation Procedures

The parameters can be estimated by means other than the maximum likelihood and the REML. Extended generalized least squares (EGLS) can be used when the observations at least conceptually represent series of observations on individuals.^[38] Write the j th observation on individual i as

$$y_{ij} = f(x_{ij}, \beta_i) + \sigma g(f(x_{ij}, \beta_i), \theta) \varepsilon_{ij} \quad (11)$$

where the parameter vector β_i for individual i is drawn from a distribution (usually assumed p -variate normal) with mean β and covariance matrix Σ . The within-individual errors ε_{ij} are assumed independently and identically

distributed with zero mean and unit variance. The scale parameter σ and the variance function $g()$ allow for heterogeneity because of the intra-individual correlation. An analog to REML estimation can be applied to EGLS estimators as well. The general formulation provides a unified basis for a number of variations on this theme.^[39–45]

The analyses can also be carried out using Bayesian^[46–57] or empirical Bayesian^[58] methods, which start with a likelihood for the observations based on a model such as Eq. 2 or 11, and then append expressions for prior distributions of the various parameters to obtain an expression for the joint distribution of the data and the parameters. Integrating with respect to the model (likelihood) parameters yields a marginal distribution for the observations that depends at most on the (known) parameters of the prior distributions. Dividing the joint distribution of the data and the model parameters by this marginal distribution gives the posterior distribution of the model parameters. Inferences about the parameters and about the functions of the parameters (for example, tolerance limits or predictive limits for future observations) are based on the posterior distribution. The difficult part of the computation is the integration to produce the marginal distribution of the observations. One can partly avoid the problem by approximating the mean of the posterior distribution by its mode.^[55] Current practice employs Markov Chain Monte Carlo techniques^[48,53] that sample from conditional posterior distributions in such a way as to generate samples from the full joint posterior distribution. These can be summarized by appropriate techniques to yield summary statistics and descriptions of the posterior distributions.^[59,60] Markov Chain Monte Carlo methods are powerful tools for analyzing mixed models, both linear and non-linear. However, the results they provide need to be checked carefully to assure that the assumptions on which they are based are met, notably that the realizations from the sampling process comprise independent (or at least uncorrelated) stationary series.

SMALL SAMPLE ADJUSTMENTS

For small sample problems, the ML or REML method for estimating fixed effects β and variance components as well as the inference for fixed effects that are based on the asymptotic distribution of $\hat{\beta}$ may be inadequate when ignoring the variability in the $\hat{\mathbf{V}} = \mathbf{V}(\hat{\theta})$ in Eq. 7. For certain combinations of covariance structure, design, and sample size, this can seriously overestimate the true precision of $\hat{\beta}$. Further, Wald-type test procedures and corresponding confidence intervals that are based on asymptotic chi-squared approximations also ignore the variability in the estimate of variance components.

The investigation of approximating the small sample precision of $\hat{\beta}$ and related distributional issues can be dated back to the work by Harville and coworkers.^[61–66] Kenward and Roger^[67] combined these results and further developed

a method that adjusted the bias of the inference for fixed effects caused by ignoring the variability in the estimate of θ when only limited number of observations was involved in the model.

When EGLS is employed to make the inference for the fixed effects, in addition to $\hat{\mathbf{V}} = \mathbf{V}(\hat{\theta})$, the variability in estimating fixed effects may also contribute to overestimating the true precision through the estimate of its variance-covariance matrix that also depends on $\hat{\beta}$. This problem has been investigated in several studies that have proposed different directions to correct the bias including correcting the empirical residuals utilized to estimate the variance-covariance matrix,^[68–70] correcting the degrees of freedom when making the inference,^[70,71] and using experiencing formulae.^[72]

NON-LINEAR MODELS

As noted in “Introduction,” the essential difference between non-linear and linear models is the expression of the expectation of the observation vector as a non-linear function $f()$ of the covariates and parameters instead of a linear function. The functional form of f may be obtained from previous studies, derived from the theory based on fundamental physical or biological principles, or represent empirical description of observations, e.g., from a graphical display of data. The functional form of f ordinarily is assumed known. Analyses can be carried out without assuming that f is known by using a spline approximation to f or using generalized additive models.^[73]

Random effects can enter the model non-linearly as well as linearly. This occurs, for example, in generalized linear models and in survival analyses, where the random effects scale the hazard function. Inference in these cases can be considerably more complicated than when the effects enter linearly, and standard methods often cannot be applied. Several approaches often used to deal with this problem: extended general linear models as described in “Other Estimation Procedures,” where parameters are estimated for each individual in the sample and are then combined; approximation of the non-linear model by a first-order Taylor series expansion that effectively linearizes it;^[43,74,75] the semi-non-parametric method;^[76] the fully Bayesian analysis,^[77] and Laplace’s approximation.^[78]

SOFTWARE

The computations required for the analysis of mixed models range from intensive to very intensive. Standard software packages usually include some facility for analyzing linear mixed models for continuous, normally distributed data. Some of these packages are commercial, and some are available free of charge. Packages are also available to carry out calculations for non-linear models,

e.g., logistic mixed models, ordinal regression, Poisson regression, etc. The availability of the diagnostic procedures to test the validity of the results of computer-intensive methods is an important consideration in the choice of a software package.

Mixed-Outcome Data

A. R. de Leon

Department of Mathematics and Statistics, University of Calgary, Calgary, Alberta, Canada

Abstract

In this entry is provided an up-to-date, comprehensive, and unified overview of available strategies for modeling and analyzing mixed outcomes, highlighted by connections between various approaches and research threads in the literature, paying particular attention to their advantages and disadvantages.

Keywords: Copulas; General location model; Logistic regression; Maximum likelihood; Poisson outcomes; Probit regression; Pseudolikelihood; Random-effects models.

INTRODUCTION

Mixed outcomes are ubiquitous in applications in health and medicine, and joint analysis of such outcomes entails specification of models flexible enough to accommodate them. Such joint models are potentially advantageous in several statistical and practical respects. For example, intrinsically multivariate questions concerning relationships between outcomes and the joint influence of covariates on them may be easily answered by fully exploiting the multivariate nature of the data through joint models. From a statistical standpoint, joint analysis avoids multiple testing and naturally leads to global tests, thus resulting in increased power and better control of type I error rates. Significant efficiency gains over separate univariate analyses have also been reported, especially in settings where there are missing data (e.g., Ref. [1]). The following are examples of studies where mixed outcomes are of interest.

Example 1

(Macular degeneration study) Longitudinal data are obtained from a two-armed randomized multi-center clinical trial on visual acuity of patients suffering from macular degeneration. In the trial, a patient's visual acuity was assessed at different time points through his ability to read lines of letters on standardized vision charts displaying line letters of decreasing size that he must read from top (largest letters) to bottom (smallest letters). Each line with at least four letters correctly read is called one line of vision. The data consist of a true count endpoint, corresponding to the total number of letters correctly read, and a surrogate binary endpoint, defined as the loss of at least three lines of vision at one year compared with their baseline performance. The study aim is to investigate the relationship between the mixed endpoints. See also Molenberghs and Verbeke^[2] and Pinto and Normand.^[3]

Example 2

(Irwin's toxicity study) The data come from a three-day repeated dose-toxicity study on neurofunctional effects of a psychotropic drug on rats. The data consist of several binary outcomes relating to behavior, including locomotor activity—characterized by the animal's abnormal biting, restlessness, writhing—and positional passivity—defined as an animal's struggle response to sequential handling—and a number of continuous outcomes, such as body temperature, pupil size, and so forth. The goal of the study is to determine treatment effects as well as the association between certain mixed outcomes. Details are given in Faes et al.^[4]

Example 3

(Veterans' Health Administration health performance monitoring study) The study collected monitoring data on health performance of several geographically defined service networks in the United States, with the objective of characterizing the quality of care of different service networks. The observed data consist of multi-level continuous and discrete outcomes collected repeatedly within clusters over time, and consist of mixed continuous and binary variables on visits, days between visits, readmissions, days between readmissions, and so on, from a sample of veterans. The goal of the study is to characterize trends in quality of individual service networks on the basis of the mixed outcomes and to identify problems in quality for specific networks. Details are found in Daniels and Normand.^[5]

In analyzing such mixed-outcome data, emphasis is usually placed on determining the joint distribution of the mixed outcomes, from which are obtained specific aspects of their relationships, such as marginal and conditional distributions, and associations. Most research dealing with statistical problems associated with joint analysis of mixed outcomes has appeared only recently due to difficulties in

specifying a mixed-outcome joint distribution and the relative lack of standard models. This is further compounded in longitudinal and cluster data settings in medical and health studies, where associations between mixed outcomes at various levels need to be meaningfully delineated in the analysis.

In this contribution, we provide an up-to-date, comprehensive, and unified overview of available strategies for modeling and analyzing mixed outcomes. We highlight connections between various approaches and research threads in the literature, paying particular attention to their advantages and disadvantages. Several examples provide background material on the assorted challenges that arise in the analysis of mixed outcomes.

JOINT MIXED-OUTCOME MODELS

A number of joint modeling strategies for mixed outcomes have been studied in the literature. The general approach first specifies a model for the joint distribution of mixed outcomes, then fits the model to data at hand, and finally uses the model to draw inferences. The challenge is that such multivariate distributions are uncommon.

Consider a mixed-data set-up represented by the vectors $\mathbf{X}_i$ and $\mathbf{Y}_i$ denoting discrete (e.g., nominal or ordinal categorical variables, counts) and continuous outcomes, respectively, observed from subject $i = 1, \dots, n$. Joint analysis of X_i and Y_i requires either direct or indirect specification

of the joint density $f_{\mathbf{X}_i, \mathbf{Y}_i}(\mathbf{x}, \mathbf{y})$. Models for the analysis of continuous outcomes have been well studied; however, only recently have researchers begun tackling the corresponding problems associated with discrete outcomes. Examples of earlier work in this area include the multivariate probit model and the so-called Dale model (see^[2] for more details). Although these have paved the way for advances in mixed-outcome data analysis,^[6,7] there is no standard model similar to the multivariate normal distribution for continuous data or the multinomial distribution for discrete variables, resulting in a dearth of models. A taxonomy of currently available modeling approaches for mixed outcomes is shown in Fig. 1.

In the next section, we survey various models for $f_{\mathbf{X}_i, \mathbf{Y}_i}(\mathbf{x}, \mathbf{y})$, many developed for specific applications and mostly based on some factorization of it into marginal and conditional components. A number of issues concerning their application to joint regression modeling of mixed-outcome data are discussed. These issues involve model specification as well as ensuing inference based on such models.

FACTORIZATION MODELS

One of the earliest proposals of directly specifying the joint distribution factorizes it into a conditional distribution of one set of outcomes and a marginal distribution of the other set.

Fig. 1 Taxonomy of models for mixed outcomes X (discrete) and Y (continuous)

This suggested two formulations of mixed-outcome joint distributions: (i) a marginal distribution for discrete outcomes and a conditional distribution for continuous outcomes, given discrete outcomes and (ii) a marginal distribution for continuous outcomes and a conditional distribution for discrete outcomes, given continuous outcomes.

Formulation (i) has received much attention in mixed-data literature, the most popular such approach being Olkin and Tate's^[8] so-called general location model (GLOM). The model is a special case of conditional Gaussian distributions used in graphical association models of mixed data, and assumes different multivariate normal distributions for continuous outcomes given discrete outcomes, and a marginal multinomial distribution for the latter.

Example 4

(Logistic-normal model) Consider a binary outcome X_i and a continuous outcome Y_i . Given outcome-specific covariates $\mathbf{z}_{x_i}$ and $\mathbf{z}_{y_i}$, a marginal regression model for X_i and a conditional regression model for Y_i given X_i are specified as

$$\log\left(\frac{\mu_{x_i}}{1-\mu_{x_i}}\right) = \mathbf{z}_{x_i}^T \boldsymbol{\beta}_x \text{ and } \mu_{y_i|x_i} = \mathbf{z}_{y_i}^T \boldsymbol{\beta}_y + \gamma(X_i - \mu_{x_i}),$$

where $\mu_{x_i} = P(X_i = 1)$ and $\mu_{y_i|x_i} = E(Y_i | X_i)$. With $Y_i | X_i \sim \text{normal}(\mu_{y_i|x_i}, \sigma^2)$ and $X_i \sim \text{bernoulli}(\mu_{x_i})$, the joint density of X_i and Y_i is then

$$f_{X_i, Y_i}(x, y) = f_{X_i}(x) f_{Y_i|x_i}(y | x) = \frac{1}{\sigma} \phi\left(\frac{y - \mu_{y_i|x_i}}{\sigma}\right) \exp\left\{\eta_{x_i} x - \log(1 + e^{\eta_{x_i}})\right\},$$

where $\eta_{x_i} = \log\{\mu_{x_i}/(1-\mu_{x_i})\}$ and $\phi(\cdot)$ is the standard normal density. The association between X_i and Y_i is induced by γ as follows:

$$\text{corr}(X_i, Y_i) = \frac{\gamma}{\sqrt{\gamma^2 + \frac{\sigma^2}{\mu_{x_i}(1-\mu_{x_i})}}}.$$

Note that X_i and Y_i are uncorrelated whenever $\gamma = 0$.

The logistic-normal model extends GLOM to incorporate marginal regression models for binary and continuous outcomes. A number of refinements and extensions of the logistic-normal model have since been studied by several authors. Fitzmaurice and Laird^[9] adapt this model to mixed data with missing responses.

An example of formulation (ii) is the so-called conditional grouped continuous model (CGCM), which assumes a logistic or probit conditional distribution for binary given continuous outcomes and a marginal multivariate normal distribution for the latter. In such models, a continuous latent

vector $\mathbf{Y}_i^*$ underlying $\mathbf{X}_i$ is supposed to exist and a joint distribution $f_{Y_i^*, Y_i}(y^*, y)$ is assumed for $\mathbf{Y}_i^*$ and Y_i . A threshold model is then postulated for $\mathbf{X}_i$ and its corresponding latent vector $\mathbf{Y}_i^*$, so that $f_{X_i, Y_i}(x, y) = f_{Y_i}(y) f_{X_i|Y_i}(x | y)$ is specified through $f_{Y_i^*, Y_i}(y^*, y) = f_{Y_i}(y) f_{Y_i^*|Y_i}(y^* | y)$. Although $f_{Y_i^*, Y_i}(y^*, y)$ is completely arbitrary, modeling it as multivariate normal is convenient because of the latter's convenient marginal and conditional distributional properties.

Example 5

(Probit-normal model) Consider again binary and continuous outcomes X_i and Y_i in Example 4. To model the joint distribution of X_i and Y_i , let $Y_i \sim \text{normal}(\mu_{y_i}, \sigma^2)$ and assume, underlying X_i , a continuous latent variable Y_i^* such that $X_i = I\{Y_i^* > 0\}$, where Y_i and Y_i^* are jointly normal with correlation ρ . With $\mu_{y_i} = \mathbf{z}_{y_i}^T \boldsymbol{\beta}_y$ and $\mu_{y_i^*} = \mathbf{z}_{x_i}^T \boldsymbol{\beta}_{x|y}$, the joint density of X_i and Y_i is

$$f_{X_i, Y_i}(x, y) = \left\{ \Phi\left(\frac{\mathbf{z}_{x_i}^T \boldsymbol{\beta}_{x|y}}{\sqrt{1-\rho^2}} + \gamma(y - \mu_{y_i})\right) \right\}^x \times \left\{ 1 - \Phi\left(\frac{\mathbf{z}_{x_i}^T \boldsymbol{\beta}_{x|y}}{\sqrt{1-\rho^2}} + \gamma(y - \mu_{y_i})\right) \right\}^{1-x} \times \frac{1}{\sigma} \phi\left(\frac{y - \mu_{y_i}}{\sigma}\right),$$

where $\gamma = \rho/(\sigma\sqrt{1-\rho^2})$ and $\Phi(\cdot)$ is the standard normal distribution function. We also get

$$\text{corr}(X_i, Y_i) = \frac{\text{cov}\left(\Phi\left(\frac{\mathbf{z}_{x_i}^T \boldsymbol{\beta}_{x|y}}{\sqrt{1-\rho^2}} + \gamma(Y_i - \mu_{y_i})\right), Y_i\right)}{\sigma \sqrt{\Phi\left(\frac{\mu_{y_i^*} + \gamma\mu_{y_i}}{\sqrt{1+\gamma^2\sigma^2}}\right) \left[1 - \Phi\left(\frac{\mu_{y_i^*} + \gamma\mu_{y_i}}{\sqrt{1+\gamma^2\sigma^2}}\right)\right]}}.$$

For identifiability, it is necessary that Y_i^* has unit variance. In addition, $\boldsymbol{\beta}_{x|y}$ must contain an intercept because the cutpoint was arbitrarily taken as 0. Note that X_i and Y_i are uncorrelated whenever $\gamma = 0$.

Adaptations of the probit-normal model to clustered data settings are discussed in Refs. [6,10].

De Leon and Carrière^[11] describe the general mixed-data model (GMDM) as a hybrid of GLOM and CGCM and provide a unified treatment of these two standard mixed-data models. An attractive feature of GMDM is that it incorporates associations and correlations between different outcomes and accounts for their measurement levels. The model can serve as a platform for extending conventional multivariate methods to the case of mixed data with discrete and continuous outcomes.

Asymmetry in Treatment of Outcomes

It is common to rely on the “arrow of time” to order outcomes and decide the direction of conditioning. However, many mixed-outcome models use a structural approach to classify them into continuous or discrete. Factorization models induce a hierarchy in outcomes, with the conditioning outcome treated as intermediate variable, and the conditioned outcome as the ultimate response.

Example 6

(Probit-normal model) Consider Example 5 again. It is easy to see that

$$\mu_{x_i|y_i} = P(X_i = 1 | Y_i = y) = \Phi \left(\frac{\mathbf{z}_i^T \boldsymbol{\beta}_{x|y}}{\sqrt{1 - \rho^2}} + \gamma(y - \mu_{y_i}) \right),$$

so that the marginal model becomes

$$\mu_{x_i} = P(X_i = 1) = \Phi \left(\frac{\mu_{y_i}^* + \gamma \mu_{y_i}}{\sqrt{1 + \gamma^2 \sigma^2}} \right) = \Phi \left(\mathbf{z}_i^T \boldsymbol{\beta}_x + \mathbf{z}_i^T \bar{\boldsymbol{\beta}}_y \right),$$

where $\boldsymbol{\beta}_x = \boldsymbol{\beta}_{x|y} / \sqrt{1 + \gamma^2 \sigma^2}$. Note that the marginalized probit model for X_i includes the regression coefficient $\bar{\boldsymbol{\beta}}_y = \gamma \boldsymbol{\beta}_y / \sqrt{1 + \gamma^2 \sigma^2} = \rho \boldsymbol{\beta}_y / \sigma$.

Observe that the probit-normal model reverses the factorization in the logistic-normal model. Conditioning on continuous outcomes in this case suggests a predictive model where discrete outcomes are the responses of true interest with continuous outcomes serving as “explanatory” variables. This may not be appropriate in many practical applications, where a more symmetrical treatment of outcomes is needed.

Direction of Conditioning

Factorization models are not invariant to the direction of conditioning taken and the factorization adopted. Although ideally dictated by subject-matter considerations, the choice of the direction of conditioning is mainly for statistical convenience. In toxicological studies, where such models were first developed, the biological mechanism is not well understood, variations of logistic-normal and probit-normal models have thus been studied. The resulting models are not comparable, as parameters have different interpretations depending on the factorization used.

Example 7

(Logistic-normal vs. probit-normal models) From the logistic-normal model, $\mu_{y_i} = E(Y_i) = \mathbf{z}_i^T \boldsymbol{\beta}_y$, so that regression parameters $\boldsymbol{\beta}_x$ and $\boldsymbol{\beta}_y$ have marginal interpretations. This is not true of the probit-normal model. For example, the interpretation

of $\boldsymbol{\beta}_{x|y}$ is conditional on continuous outcome Y_i ; the marginal covariate effect $\boldsymbol{\beta}_x$ is obtained by averaging over Y_i . The logistic-normal model also suggests a normal-mixture marginal distribution for Y_i with

$$\text{var}(Y_i) = \gamma^2 \mu_{x_i} (1 - \mu_{x_i}) + \sigma^2,$$

implying that the variance of Y_i depends on covariate $\mathbf{z}_i$. This contrasts with the homogeneity of Y_i in the probit-normal model.

Another drawback of factorization models is that they do not easily extend to the setting of multiple mixed outcomes. No easy expressions can be obtained for associations between outcomes as well. It is also possible for models to yield very different estimates of the associations.^[10]

RANDOM-EFFECTS MODELS

Indirect approaches to specifying mixed-outcome joint distributions have also been studied. One approach that has found widespread adoption in practice introduces shared or correlated random effects to incorporate correlations between mixed outcomes in the resulting joint model. Daniels and Normand^[5] use this strategy, albeit in a Bayesian framework, to profile health care units. Applications to high-dimensional mixed data analysis are provided by Faes et al.^[4]

The basic idea in this approach is to use random effects, either shared or correlated, to build in correlation between mixed outcomes. The approach does not resort to factorization, and thus yields a symmetrical treatment of mixed outcomes. Its hierarchical structure allows for considerable flexibility in accounting for different measurement levels, delineation of various associations, incorporation of covariate effects, and extension to longitudinal and clustered data settings. Details can be found in Refs. [2,12].

Shared Random Effects

Although random effects provide a general and versatile route for incorporating in the model various correlations between outcomes and differences in measurement levels, they are not without their shortcomings. McCulloch^[12] illustrates a problem for the case of one binary outcome and one continuous outcome, with respective conditional Bernoulli and normal distributions, given a shared normal random effect, which induces correlation between outcomes.

Example 8

(Probit-normal model with shared random effect) Consider a binary outcome $X_i \sim \text{bernoulli}(\mu_{x_i})$ and a continuous outcome $Y_i \sim \text{normally}(\mu_{y_i}, \sigma^2)$. A random effect shared by X_i and Y_i is introduced as follows:

$$\Phi^{-1}(\mu_{x_i|y_i}) = \mathbf{z}_{x_i}^T \boldsymbol{\beta}_{x|u} + U_i \text{ and } \mu_{y_i|u} = \mathbf{z}_{y_i}^T \boldsymbol{\beta}_{y|u} + \lambda U_i,$$

where $U_i \sim \text{normal}(0, \tau^2)$, with X_i and Y_i conditionally independent given U_i . The coefficient λ adjusts for difference in scales between the outcomes. The joint density is

$$f_{X_i, Y_i}(x, y) = \frac{1}{\sigma \tau} \int_{-\infty}^{\infty} \mu_{x_i|u}^x (1 - \mu_{x_i|u})^{1-x} \phi\left(\frac{y - \mu_{y_i|u}}{\sigma}\right) \phi(u) du.$$

We also get

$$\text{corr}(X_i, Y_i) = \sqrt{\frac{\lambda^2 \tau^2}{\sigma^2 + \lambda^2 \tau^2}} \frac{\text{cov}\left(\Phi\left(\mathbf{z}_{x_i}^T \boldsymbol{\beta}_{x|u} + U_i\right), \lambda U_i\right)}{\sqrt{\Phi\left(\mathbf{z}_{x_i}^T \boldsymbol{\beta}_x\right)\left\{1 - \Phi\left(\mathbf{z}_{x_i}^T \boldsymbol{\beta}_x\right)\right\}}},$$

where $\boldsymbol{\beta}_x = \boldsymbol{\beta}_{x|u} / \sqrt{1 + \tau^2}$.

With a conditional probit link for binary outcome X_i given random effect U_i , the marginal regression parameter $\boldsymbol{\beta}_x$ is smaller than the conditional regression parameter $\boldsymbol{\beta}_{x|u}$ by a factor $\sqrt{1 + \tau^2}$. In practical applications where interest lies in marginal effects of covariates, this lack of a marginal interpretation may be considered unattractive. In addition, the model constrains the correlation between X_i and Y_i . McCulloch^[12] shows that $\text{corr}(X_i, Y_i) \rightarrow \sqrt{2/\pi} \approx 0.798$ as $\tau^2 \rightarrow \infty$ with σ^2 fixed.

The situation is somewhat better in the Poisson-normal case in that marginal and conditional regression coefficients, with the exception of intercepts, are identical; however, the correlation becomes even more problematic, being integrally tied to overdispersion in the Poisson outcome. Details are discussed in Ref. [12].

Correlated Random Effects

A possible remedy to the shortcomings of the shared random effect approach is to allow for separate but correlated random effects. This results in models that more flexibly describe correlations between mixed outcomes. The following example involving count and continuous outcomes with correlated random effects is discussed in detail by McCulloch.^[12]

Example 9

(Poisson-normal model with correlated random effects) Consider a count outcome $X_i \sim \text{poisson}(\mu_{x_i})$ and a continuous outcome $Y_{it} \sim \text{normal}(\mu_{y_i}, \sigma^2)$. It is assumed that the continuous outcome is repeatedly observed over time $t = 1, \dots, n_i$, to identify subject-to-subject variation. Correlated random effects for X_i and Y_{it} are introduced as follows:

$$\log(\mu_{x_i|u_t}) = \mathbf{z}_{x_i}^T \boldsymbol{\beta}_{x|u} + U_i \text{ and } \mu_{y_i|u_t} = \mathbf{z}_{y_i}^T \boldsymbol{\beta}_{y|u} + \lambda U_i,$$

where U_{x_i} and U_{y_i} are jointly normally distributed with $E(U_{x_i}) = E(U_{y_i}) = 0$, $\text{var}(U_{x_i}) = \tau_x^2$, $\text{var}(U_{y_i}) = \tau_y^2$, and $\text{corr}(U_{x_i}, U_{y_i}) = \rho$. It is straightforward to show that

$$\text{corr}(X_i, Y_{it}) = \frac{\rho T_x T_y \exp\left(\mathbf{z}_{x_i}^T \boldsymbol{\beta}_{x|u} + \frac{1}{2} |\rho| \tau_x^2\right)}{(\sigma^2 + \tau_y^2) \left\{ \mu_{x_i} + \mu_{x_i}^2 (e^{\tau_x^2} - 1) \right\}},$$

with $\mu_{x_i} = \exp(\mathbf{z}_{x_i}^T \boldsymbol{\beta}_{x|u} + \tau_x^2/2)$.

In the Poisson-normal model in Example 9, correlated normal random effects allow for negative correlations between outcomes. It is also easier to disentangle overdispersion in the Poisson outcome, as this now depends on the covariance matrix of the random effects.^[12] However, allowing for correlated random effects in high-dimensional problems may not be computationally feasible^[4] in practice.

Random Effects Plus Correlated Errors

Still another alternative is to add correlated error terms to models for the outcomes. To see how this can be done, assume $\mathbf{X}_i$ and $\mathbf{Y}_i$ to be conditionally independent, given an unobserved random effect U_i . Generalized linear mixed models for $\mathbf{X}_i$ and $\mathbf{Y}_i$ are then specified, either via an exponential family or a marginal moments specification. Random effect U_i is subject-specific and accounts for correlation patterns of unobserved heterogeneity; to account for residual correlations, marginal models are assumed for the outcomes, in addition to random effect U_i . Specifically, we have

$$\begin{pmatrix} \mathbf{X}_i \\ \mathbf{Y}_i \end{pmatrix} = \begin{pmatrix} \mathbf{h}_{x_i}(\mathbf{U}_{x_i}, \mathbf{z}_{x_i}) \\ \mathbf{h}_{y_i}(\mathbf{U}_{y_i}, \mathbf{z}_{y_i}) \end{pmatrix} + \begin{pmatrix} \boldsymbol{\epsilon}_{x_i} \\ \boldsymbol{\epsilon}_{y_i} \end{pmatrix} = \mathbf{h}(\mathbf{U}_i, \mathbf{z}_i) + \boldsymbol{\epsilon}_i,$$

where the inverse link functions in $\mathbf{h}(\cdot, \cdot)$ depend on outcome types, and $\mathbf{z}_i$ is a vector of covariates. For discrete outcomes such as binary outcomes and counts, data approximation based on linearization may be adopted. Note that $\mathbf{h}(\cdot, \cdot)$ allows for a non-additive specification of fixed and random effects in the link function; it is also possible to incorporate latent variables for discrete outcomes. Correlations between $\mathbf{X}_i$ and $\mathbf{Y}_i$ are induced by covariance matrices of $\mathbf{U}_i$ and $\boldsymbol{\epsilon}_i$.

Example 10

(Repeated measures logistic-normal model with random effects and errors) Let X_{it} and Y_{it} be binary and continuous outcomes for subject $i = 1, \dots, n$, at time $t = 1, \dots, n_i$. The model is given by

$$\begin{pmatrix} X_{it} \\ Y_{it} \end{pmatrix} = \begin{pmatrix} \frac{\exp(\mathbf{z}_{x_{it}}^T \boldsymbol{\beta}_{x_{it}} + U_{x_{it}})}{1 + \exp(\mathbf{z}_{x_{it}}^T \boldsymbol{\beta}_{x_{it}} + U_{x_{it}})} \\ \mathbf{z}_{y_{it}}^T \boldsymbol{\beta}_{y_{it}} + U_{y_{it}} \end{pmatrix} + \begin{pmatrix} \varepsilon_{x_{it}} \\ \varepsilon_{y_{it}} \end{pmatrix},$$

where $U_{x_{it}}$ and $U_{y_{it}}$ are as defined in Example 9, with independent errors $\varepsilon_{x_{it}}$ and $\varepsilon_{y_{it}}$. Faes et al.^[4] derive a first-order approximation for the correlation between X_{it} and Y_{it} as

$$\text{corr}(X_{it}, Y_{it}) \approx \frac{\rho \tau_x T_y v_{it}}{\sqrt{v_{it} (1 + v_{it} \tau_x^2) (\tau_y^2 + \sigma^2)}},$$

$$\text{var}(\varepsilon_{x_{it}}) \approx v_{it} = \frac{\exp(\mathbf{z}_{x_{it}}^T \boldsymbol{\beta}_{x_{it}}) \{1 - \exp(\mathbf{z}_{x_{it}}^T \boldsymbol{\beta}_{x_{it}})\}}{\{1 + \exp(\mathbf{z}_{x_{it}}^T \boldsymbol{\beta}_{x_{it}})\}^2}$$

and $\text{var}(\varepsilon_{y_{it}}) = \sigma^2$

The inclusion of random effects in the above model accounts for correlations between repeated measurements. In the case of independent random effects, the outcomes are approximately marginally uncorrelated. Incarnations of the above model, with varying levels of generality, are given by Faes et al.,^[4] Gueorguieva and Sanacora,^[1] and Gueorguieva and Agresti.^[13] Bayesian versions of the model have been studied by Daniels and Normand^[5] and Dunson,^[14] among others. This approach is quite attractive; however, for Poisson outcomes, for example, it leads to the same problem of overdispersion being built into the model, as what happens in the shared random effect approach.^[12]

OTHER MODELS

A number of other alternative models have been proposed and studied by various authors. A Plackett-Dale distribution has been used by Molenberghs et al.^[15] as an alternative to multivariate normal distributions for latent variables. The quadratic exponential model, which has a general form that can accommodate mixed outcomes, has been adopted by Sammel et al.^[16] in clustered settings. The model considers conditional log-odds ratios as measures of associations and requires a normalizing constant, the computational demands of which can be prohibitive in certain cases. Regan and Catalano^[17] introduced mixed-probit models for binary and continuous outcomes that, unlike factorization-based models, treat outcomes in a more symmetrical fashion and have marginal interpretations for their regression parameters. However, these models were developed for specific applications, and thus, may lack generality and flexibility to be applied in other mixed-outcome data settings.

Finally, several authors have adopted copula functions to indirectly specify mixed-outcome joint distributions. This is only a recent phenomenon in modeling mixed outcomes, and unresolved issues, both methodological and practical, abound, especially as they apply to discrete data.

Example 11

(Robit-normal model) To model the joint distribution of binary outcome X_i and continuous outcome Y_i , we let $Y_i \sim N(\mu_{y_i}, \sigma^2)$ and assume, underlying X_i , a continuous latent variable $Y_i^* \sim t_1(\mu_{y_i^*}, 1, \nu)$, i.e., the univariate (generalized) t -distribution with mean $\mu_{y_i^*}$, unit scale, and degrees of freedom ν , such that $X_i = I\{Y_i^* > 0\}$.

With $\mu_{y_i} = \mathbf{z}_{y_i}^T \boldsymbol{\beta}_{y_i}$ and $\mu_{y_i^*} = \mathbf{z}_{x_i}^T \boldsymbol{\beta}_{x_i}$, and using the Gaussian copula, de Leon and Wu^[18] derive the joint density of X_i and Y_i as

$$f_{X_i, Y_i}(x, y) = \left\{ \Phi \left(- \frac{\Phi^{-1}(w_i) - \rho \left(\frac{y - \mu_{y_i}}{\sigma} \right)}{\sqrt{1 - \rho^2}} \right) \right\}^x$$

$$\times \left\{ 1 - \Phi \left(- \frac{\Phi^{-1}(w_i) - \rho \left(\frac{y - \mu_{y_i}}{\sigma} \right)}{\sqrt{1 - \rho^2}} \right) \right\}^{1-x} \frac{1}{\sigma} \phi \left(\frac{y - \mu_{y_i}}{\sigma} \right),$$

where $w_i = P(X_i = 1) = P(Y_i^* > 0)$ and ρ is the Pearson correlation between so-called normal scores $\Phi^{-1}\{P(Y_i^* \leq 0)\}$ and $\Phi^{-1}\{P(Y_i^* \leq 0)\}$, a “proxy” for the tetrachoric correlation between X_i and Y_i .

Liu^[19] introduces the term robit regression based on a t -latent distribution as a robust alternative to and extension of logit and probit regression models. Liu^[19] shows that robit models approximate both logit (with $\nu \approx 7$) and probit (with large ν) regressions, and thus provide a general approach to binary regression modeling.

Copula functions, which are common in actuarial and financial applications, have proved useful in practice when the joint distribution of interest is either not available or difficult to specify but marginal distributions can be specified with confidence, like in mixed-outcome data settings. The approach entails specifying marginal distributions $f_{X_i}(x)$ and $f_{Y_i}(y)$, and combining them to form a joint distribution via a suitable copula function. Note that, similar to random effects approaches, copula-based models treat mixed outcomes symmetrically; however, unlike factorization and random effects models, their regression parameters are marginally meaningful. Recent applications of copulas to mixed outcomes are discussed in Song^[20,21] and Hoff.^[22]

MODEL ESTIMATION

A variety of approaches have been considered in the literature for model estimation. Given a full specification of the model, a likelihood-based approach may be considered. However, evaluation and direct maximization of the full likelihood may be computationally prohibitive in practice. In addition, a full likelihood approach raises questions about the robustness of the likelihood specification quite apart from any computational difficulties. To circumvent these, the full likelihood may be replaced by a more computationally tractable function, a so-called pseudo-likelihood function. One such function is obtained by compositing pairwise likelihoods over the data. Faes et al.^[23] adopts this strategy in a high-dimensional mixed-outcome analysis via mixed models implemented using standard software, such as SAS procedures NLMIXED and glimmix. Working with such a modification of the likelihood function generally yields consistent estimates of model parameters, including correlations under a range of possible models for higher-order dependency as captured by the full joint distribution. Computational and statistical performance of these methods has been shown to range from acceptably good to excellent.

Several alternative estimation strategies based on the EM and Monte Carlo methods have also been proposed in the literature.^[16] However, as with conventional full likelihood estimation, these methods have the disadvantage of excessive computational requirements. Non-likelihood based approaches such as generalized estimating equations (GEE)^[3] may also be adapted to this context. These may prove more useful and computationally more feasible than likelihood-based methods in practice.

CONCLUSION

This contribution provides an up-to-date survey of joint analysis of mixed outcomes. Both direct and indirect approaches to joint model specification are discussed along with their advantages and disadvantages. Because correlations between the mixed outcomes are usually of practical interest, particular attention is given to differences in how such correlations are incorporated in the models. Technical and practical issues relating to model estimation are also briefly discussed, with focus on pseudo-likelihood methods.

The use of copulas in modeling mixed outcomes is a recent phenomenon. Because of this, unresolved issues, both methodological and practical, abound. One is the paucity, if not total lack, of copulas that can be used for mixed outcomes; of theoretical, but of lesser practical, concern is the non-uniqueness of copulas for discrete outcomes. Another involves the interpretation of the dependence parameter of copula functions, a serious problem for discrete distributions. De Leon and Wu^[18]

have developed copula-based regression models for mixed outcomes by adopting a latent-variable formulation of the discrete outcomes and using Gaussian copulas to “glue” mixed-outcome marginal regression models. Work on generalizations of their approach to high-dimensional settings with possibility of incorporating random effects would be worthwhile. The challenge here lies in defining models that allow for different levels of association among outcomes, as in longitudinal studies.

Incomplete data are ubiquitous in studies involving mixed outcomes.^[9] This is an area where little research has been done. Adaptations of the models discussed in this contribution to handle missing data would be of great importance in practice.

FURTHER READING

The last decade has seen many remarkable advances in statistical methodology for analyzing mixed data and we give here only a few selected references. Regan and Catalano^[17] provide an excellent early survey of mixed-outcome analysis, with particular focus on toxicological applications. Molenberghs and Verbeke^[2] provide a good introduction to generalized linear mixed models for mixed outcomes and include a number of practical examples. Faes et al.^[23] update Molenberghs and Verbeke^[2] and include recent advances in analysis of longitudinal mixed outcomes in high-dimensions. Bayesian approaches including methods for handling incomplete mixed-outcome data, are described in Daniels and Hogan.^[24] McCulloch et al.^[25] devote a chapter on random-effects models for mixed outcomes. The use of copulas for modeling mixed data is discussed in Song.^[20]

MMRM with Missing Data

Annpey Pong, Jun Zhao, Allen Lee, Phillip Phiri, and Lev Sverdlov

Merck Research Laboratories, Summit, New Jersey, U.S.A.

Abstract

In clinical research of drug development, missing values in longitudinal data are common due to early drop out. Therefore the method of handling missing values is critical in data analysis of drug development. This entry breaks down the methodology of the Mixed-effects Model Repeated Measurement and provides an example illustrating its role in the problem of missing data.

INTRODUCTION

In clinical research of drug development, missing values in longitudinal data are common due to early drop out. Missing values usually lead to a potential source of bias in data interpretation.^[1] Therefore the method of handling missing values is critical in data analysis of drug development. Particularly it's important to submission of confirmatory trials for New Drug Applications (NDA).^[2,3]

According to the ICH E9, Section 5.3, *Statistical Principles for Clinical Trials*,^[4] the methods of dealing with missing values are to be pre-defined in the protocol, or may be updated in the statistical analysis plan (SAP) during the blind review. However, there is no universally applicable method of handling missing values recommended. The sensitivity of the results to the method of handling missing values should be concerned and investigated. In current practice for NDA submissions, the method of handling missing value to the primary analysis for key efficacy variable(s) is the focus and to be clearly described in the SAP before locking the database.

In many therapeutic areas such as CNS, the general period of observation is divided into the short term acute phase (lasted from days to weeks) and the long term extension phase (lasted from weeks to years). The drop out rate in the long term phase is usually much higher than completion rate in the short term study. Effect of missing data in the long term extension studies is an additional concern and more problematic for the SAP development and statistical analysis.^[5]

Little and Rubin^[1] classified missing values into 3 categories: (i) missing completely at random (MCAR) assumes missing values are randomly distributed across all observations. In other words, missingness does not depend on either observed or unobserved outcomes; (ii) missing at random (MAR) requires missing values are randomly distributed on the observed data only. As a result, the missingness depends on the observed outcomes but not the unobserved; (iii) missing not at random

(MNAR) presumes for non-ignorable missing values. Consequently, the missingness depends on the unobserved outcomes. In reality, we cannot tell from the data at hand whether the missing observations are MCAR, MAR, or MNAR except by obtaining follow-up data from non-respondents. Nevertheless this is a non-practical approach in clinical trials.

In the past decade, the last observation carried forward (LOCF) has been a long-standing and traditional method of handling missing values for longitudinal data especially in psychiatric clinical trials. It's not uncommon that a simple endpoint analysis such as analysis of covariance (ANCOVA) is performed in longitudinal studies. For a commonly used primary efficacy variable, mean change from baseline to endpoint, the LOCF approach assumes the change to endpoint from baseline is the same as the change to the last observed value. In other words, the missing value at endpoint is imputed by the last observed value in the trial for early drop out subjects. This is based on the assumption of MCAR. Researches have shown that LOCF was not robust to handle the potential bias due to missing values and the results were often invalid.^[6–8] In addition, the LOCF does not take response profiles over time into consideration. Except the LOCF, other missing data imputation alternatives are available. The methods include the baseline observation carried forward (BOCF), worst observation carry forward (WOCF), partial LOCF (such as, BOCF for dropout due to AE, and LOCF for other dropouts), and a single imputation by using the mean value. The primary drawbacks of these methods are the underestimation of the standard error and a strong assumption of MCAR. To avoid these problems, the multiple imputation (MI) methods^[9] and maximum likelihood methodology (MLE)^[10] which require the assumption of MAR are usually considered. The primary difference between MI and MLE is MI requires additional data manipulation and modeling choice to impute missing data, but not for the MLE based on the maximum likelihood.

The Mixed-effects Model Repeated Measurement (MMRM) is a likelihood-based method which provides better control of type I and type II errors than ANCOVA based on LOCF for missing data imputation (ANCOVA-LOCF).^[11–13] The MMRM uses all the observed data from repeated measurements assuming to be multivariate normal to adjust the data which was missing on an individual subject. In drug development, the MMRM analysis was initially acceptable for primary analysis to the efficacy measurement, 17-item Hamilton Rating Scale, on confirmatory phase III trials, Duloxetine (as Cymbalta®).^[14,15] This approach took the place of the commonly used ANCOVA-LOCF for primary analysis in antidepressant products.

The mixed models for repeated data were firstly introduced into psychiatric literature by Gibbons et al.^[16] The model assumes a continuous outcome variable which is linearly related to a set of explanatory variables. The fundamental difference of mixed model to the traditional simple endpoint analysis is the repeated observations within subjects are correlated, and this correlation is incorporated into the analysis model. Usually, an unstructured variance-covariance structure is considered, or a goodness-of-fit exploration to be used to disclose the best fit from different structures. In addition, the analysis model contains both fixed and random effects. The commonly used main fixed effects are treatment group, study center, and visit for multi-center clinical trials. The random effect is usually referred to the subject's effect in the study.

The MMRM estimates for missing data are derived using EM algorithm. As a result, the EM algorithm may not converge to the maximum likelihood estimate when data are sparse, or if the rate of missing data is high, or analysis model is over-parameterized.^[17,18] The analysis for MMRM can be easily assessed using, for example, the SAS procedure MIXED or the SPlus or R function, without additional data manipulation. It is to be noted that the estimates from MMRM are valid if MAR assumption is met. The assessment of missing mechanism for MAR may be explored by odds ratio which is illustrated in a numerical example in "Example."

MMRM METHODOLOGY

General Linear Mixed Model

The general linear mixed-effect model was introduced by Laird and Ware,^[17] which contains both fixed and random effects. Let $\mathbf{y} = (y_1, y_2, \dots, y_n)$ be the n -dimensional response vector from n subjects, and the data to be explained by p fixed-effects variables $x_1, \dots, x_p$, and q random-effects variables $z_1, \dots, z_q$. Then the mixed model can be written as the following matrix format:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{\gamma} + \boldsymbol{\varepsilon}$$

where

$\mathbf{X}$ is the $(n \times p)$ -dimensional matrix associating to the observations of the fixed-effects

$\mathbf{Z}$ is the $(n \times q)$ -dimensional matrix associating to the random-effects

$\boldsymbol{\beta}$ is the p -dimensional vector of fixed-effects parameters

$\boldsymbol{\gamma}$ is the q -dimensional vector of random-effects parameters

$\boldsymbol{\varepsilon}$ is the $(n \times 1)$ -dimensional vector of errors for observations.

In addition, $\boldsymbol{\gamma}$ and $\boldsymbol{\varepsilon}$ are independently normal distributed with

$$E \begin{bmatrix} \boldsymbol{\gamma} \\ \boldsymbol{\varepsilon} \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \end{bmatrix}$$

$$Var \begin{bmatrix} \boldsymbol{\gamma} \\ \boldsymbol{\varepsilon} \end{bmatrix} = \begin{bmatrix} \mathbf{G} & \mathbf{0} \\ \mathbf{0} & \mathbf{R} \end{bmatrix}$$

where $\mathbf{G}$ is a $q \times q$ -dimensional covariance matrix for the random effects; $\mathbf{R}$ is the $(n \times n)$ covariance matrix for the errors; $\mathbf{0}$ is vector of zeroes; Note that the correlation among data within a subject and heterogeneous variances at different visits is allocated under longitudinal data structure. The variance of $\mathbf{y}$, $\mathbf{V}$, is therefore to be calculated as below:

$$\mathbf{V} = Var(\mathbf{y}) = \mathbf{Z}\mathbf{G}\mathbf{Z}' + \mathbf{R}$$

It is to be noted that the general linear model is a special case of the mixed model with $\mathbf{Z} = \mathbf{0}$ and $\mathbf{R} = \sigma^2 \mathbf{I}$

Estimating $\mathbf{G}$ and $\mathbf{R}$ in the Mixed Model

To estimate $\boldsymbol{\beta}$, generalized least squares (GLS) is used to minimize

$$(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})' \mathbf{V}^{-1} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta})$$

where $\mathbf{V}$ is the variance of $\mathbf{y}$. It becomes clear that we need to estimate $\mathbf{G}$ and $\mathbf{R}$ first. Under the assumption that $\boldsymbol{\gamma}$ and $\boldsymbol{\varepsilon}$ are normally distributed, estimation of the covariance parameters ($\mathbf{G}$ and $\mathbf{R}$) can be done through (restricted) maximum likelihood methods. It has been shown^[19,20] that both methods accommodate data that are missing at random (MAR).

In addition to the assumptions to $\boldsymbol{\gamma}$ and $\boldsymbol{\varepsilon}$, we may further assume that $\mathbf{R}$ and/or $\mathbf{G}$ follow some variance-covariance structures. The variance-covariance structures like compound symmetry (CS), AR(1), toeplitz (TOEP), unstructured (UN), etc are commonly used. To test one covariance structure against the other for lack of fit, Information Criterion (IC) such as Akaike's Information Criterion^[21] and Schwarz's Bayesian Information Criterion^[22] are frequently used. The rule is the smaller IC the better fit. One can also use the likelihood ratio to test whether one model is significantly better than the other.

Estimating β and γ in the Mixed Model

Let $\hat{G}$ and $\hat{R}$ be the estimates of G and R , respectively. To obtain estimates of β and γ , the standard method is to solve the *mixed model equations*^[23] as below:

$$\begin{bmatrix} X'\hat{R}^{-1}X & X'\hat{R}^{-1}Z \\ Z'\hat{R}^{-1}X & Z'\hat{R}^{-1}Z + \hat{G}^{-1} \end{bmatrix} \begin{bmatrix} \hat{\beta} \\ \hat{\gamma} \end{bmatrix} = \begin{bmatrix} X'\hat{R}^{-1}Y \\ Z'\hat{R}^{-1}Y \end{bmatrix}$$

The solutions can be written as the empirical Bayes estimators^[17] shown below:

$$\begin{aligned} \hat{\beta} &= (X'\hat{V}^{-1}X)^{-1} X'\hat{V}^{-1}y \\ \hat{\gamma} &= \hat{G}Z'\hat{V}^{-1}(y - X\hat{\beta}) \end{aligned}$$

Note that the mixed model equations are extended normal equations. $\hat{G}$ is nonsingular. If $\hat{G}$ is singular, then the mixed model equations can be modified as shown in Henderson.^[23]

Statistical Properties and Inferences

With estimates of β and γ , hypothesis testing regarding these unknown parameters can be performed to

$$H_0 : L \begin{bmatrix} \beta \\ \gamma \end{bmatrix} = 0$$

If L consists of a single row, a general t -statistic can be computed as

$$t = \frac{L \begin{bmatrix} \hat{\beta} \\ \hat{\gamma} \end{bmatrix}}{\sqrt{L\hat{C}L'}}$$

where

$$\hat{C} = \begin{bmatrix} X'\hat{R}^{-1}X & X'\hat{R}^{-1}Z \\ Z'\hat{R}^{-1}X & Z'\hat{R}^{-1}Z + \hat{G}^{-1} \end{bmatrix}^{-1}$$

is the approximate variance-covariance matrix of $(\hat{\beta} - \beta, \hat{\gamma} - \gamma)$; $^{-1}$ denotes the generalized inverse of the coefficient matrix of the mixed model. In general, t is

approximately t -distributed and its degrees of freedom can be estimated.^[24,25]

If $\text{rank}(L) > 1$, a general F -statistic can be derived as

$$F = \frac{\begin{bmatrix} \hat{\beta} \\ \hat{\gamma} \end{bmatrix}^{-1} L'(L\hat{C}L')^{-1} L \begin{bmatrix} \hat{\beta} \\ \hat{\gamma} \end{bmatrix}}{\text{rank}(L)}$$

The numerator degree of freedom is the rank (L) and the denominator degree of freedom is taken from the corresponding fixed or random effects.

EXAMPLE

In this section, the efficacy data from a schizophrenia study is presented. This example is to describe the rational of using a mixed model for the longitudinal data, instead of a fixed effect ANCOVA model. This is a double-blind, placebo controlled 6-week study.

The efficacy assessment, total PANSS (Positive and Negative Syndrome Scale) score, were done on baseline and post-treatments on Days 4, 7, 14, 21, 28, 35 and 42. The primary interest is the change from baseline in total PANSS score at 42 days (or endpoint) on treatment. A traditional methodology is to analyze the data by using an ANCOVA model on day 42/Endpoint, with missing data imputed by LOCF.

It was observed that 61.3% of subjects finished the 42 days of treatment from four treatment groups. The reasons for discontinuation are summarized in Table 1. It shows that a relatively high percentage of drop out rate of 38.7% and unbalanced drop out due to lack of therapeutic response and withdrew consent between treatment groups. This leads a direction that the assumption of MCAR may be violated. In other words, the validity of using the traditional method of LOCF is a concern. Since this trial was a well-controlled phase III clinical study, the missing mechanism of MNAR was unlikely either.

To assess the missing mechanism of MCAR, the following approach was applied:

If missing depends on observed outcome of interest, then the assumption of MCAR does not hold.

Table 1 Drop Out Rate by Treatment Groups and Reason for Discontinuation

Reason for discontinuation(%)	Treatment 1	Treatment 2	Treatment 3	Treatment 4	Overall
AE/SAE	10.6	9.4	10.4	4.5	8.8
Underlining Disease	7.3	8.5	5.2	1.8	5.7
Lack of Efficacy	17.9	7.5	3.5	10.8	10.1
Withdrew of Consent	10.6	10.4	22.6	18.9	15.6
Lost to Follow-up	1.6	1.9	3.5	2.7	2.4
Other	2.4	3.8	0.9	0.0	1.8
Total	43.1	33.0	40.9	36.9	38.7

To verify the statement above, a generalized linear model of the probability of drop out at Day 42/Endpoint for subjects who had at least 14 days of treatment, was employed. The rationale of using Day 14 is based on the protocol defined minimal length of in-patient period of Day 14. The model is shown as below:

$$P(\text{dropout at Day 42/Endpoint}) = \text{treatment group} \\ + \text{center} + \text{baseline total PANSS score} \\ + \text{change from baseline to Day 14 of total PANSS score,}$$

where P is the probability of including the factors on the right hand side of the equation. Thereafter a 95% confidence limit of Odds Ratio from the logistic regression model was performed (Table 2).

It was observed that the lower bound of the 95% confidence limit of Odds Ratio was larger than 1 and the covariate change from baseline to Day 14 was significant (p -value is 0.002). It concludes that the subjects with a lower change from baseline to Day 14 have a higher probability to drop out on Day 42 (such as, Odds Ratio = 1.033 per PANSS unit). Consequently the assumption of MCAR does not hold since the missingness on Day 42 depends on the observed outcome on Day 14. A MMRM was performed below based on the missing mechanism of MAR.

$$\text{Change from baseline in total PANSS score} = \text{treatment} \\ + \text{center} + \text{baseline total PANSS score} \\ + \text{visit} + \text{visit} \times \text{treatment,}$$

The unstructured (UN) covariance structure was used to model the variance of the repeated PANSS total score measurements over time within subjects. The fixed

Table 2 The Odds Ratio Estimate for Change from Baseline to Day 14

Point estimate	95% Wald confidence limits	
1.033	1.012	1.055

effects in the model are treatment group, study center, visit, baseline total PANSS score and visit by treatment interaction. The random effect is referred to the subject's effect in the study. The results of comparing of 3 treatments to the reference of treatment 1 were presented in the table below on both LOCF and MMRM. The factors in ANCOVA model with LOCF imputation are treatment group, study center, and a covariate of baseline total PANSS score.

CONCLUSIONS

Missing data are an almost ever-present problem in clinical trials.^[26] A common choice in many therapeutic areas is to assess the mean change from baseline to endpoint via analysis of variance (ANOVA), with missing data imputed by carrying the last observation forward (LOCF).^[11] The LOCF has been used as the method of choice because it is simple and easy to use. LOCF assumes that the condition of the patient whose data is missing remains unchanged from the last observed value to the endpoint of the trial. In many cases, patient's condition either improves or worsens and it seldom remains constant.^[26] Carrying observation forward may therefore bias estimates of treatment effects and associated errors.^[8,16,26,27]

As noted above, Little and Rubin^[1] classified missing values into 3 categories, namely; MCAR, MAR and MNAR based on process leading to missingness and under what process different analysis methods would be appropriate to use. This implies that the method of analysis should take account the reasons leading to the missingness. However, it is difficult to tell from the data which category the missingness falls unless there is a follow-up data from non-respondents. Nevertheless, this is not an easy practice in a well-control clinical trial.

In many clinical research settings, the MAR assumption is more reasonable than the MCAR and the likelihood-based mixed-effects models offer a general

Table 3 Mean Change from Baseline to Study Endpoint using LOCF and MMRM Analysis for Intent-To-Treat Population

Methods	Statistics	Treatment 1	Treatment 2	Treatment 3	Treatment 4
LOCF	Mean Change	-10.7	-14.9	-15.4	-16.2
	SE	1.57	1.69	1.63	1.66
	Difference to Treatment 1		-4.11	-4.70	-5.48
	SE of difference		2.25	2.21	2.23

	P-value		0.038	0.020	0.004

SE: Standard Error.

framework for the longitudinal analyses.^[26] These methods are more robust to potential bias from missing data than LOCF^[16,26] and other MCAR methods. The advantages of using MMRM include; using all the available data to compensate for the data missing on a particular patient,^[12] no additional data manipulation is required to accommodate the missing data; also the analyses can be implemented using standard software such as the SAS Procedure Mixed (SAS Institute, Cary, NC).^[28]

Since missing data in clinical research will always be present and we cannot tell from data which category the missingness falls, the MMRM is suitable for both MAR and MCAR, it would be safe to use MMRM in clinical research where data is missing and use MNAR methods as sensitivity analysis. It is important to note that MMRM is one example from the family of likelihood-based analyses developed under MAR.

Modified Large Sample Method

Yonghee Lee

Forest Research Institute, Jersey City, New Jersey, U.S.A.

Abstract

Many researchers have suggested various methods for setting approximate confidence intervals on linear combinations of variance components. This entry focuses on the modified large sample method and works to detail its components and applications.

INTRODUCTION

Linear combinations of variance components are frequently considered when the parameter of interest is individual or gross variability in statistical experimental designs. Because of the lack of an exact confidence interval for a general linear combination of variance components, many researchers have suggested various methods for setting approximate confidence intervals on linear combinations of variance components. Among those methods, the Modified Large Sample (MLS) method has its merit in terms of simplicity, flexibility, and good empirical performance. Generally, the MLS method can give an approximate confidence bound on any linear combination of variance components of the following form:

$$c_1\sigma_1^2 + c_2\sigma_2^2 + \cdots + c_p\sigma_p^2 \quad (1)$$

where $\sigma_1^2, \dots, \sigma_p^2$ are variance components and $c_1, \dots, c_p$ are fixed nonzero real numbers. The idea of the MLS method was independently proposed by Howe^[1] and Graybill and Wang.^[2] The main idea of the MLS method was well described by Howe^[1] as follows: When each of the marginally exact quantiles of estimators of variance components are known, we can incorporate this knowledge into setting a good approximate confidence interval for a linear combination of variance components by interpolating the given exact quantiles.

In most clinical trials comparing a test drug and a control (e.g., a placebo control or an active control), treatment effect is usually established by comparing changes in mean responses from baseline of some primary study endpoints assuming that their corresponding variabilities are comparable. However, in practice, variabilities associated with the test drug and the control could be very different. When the variability of the test drug is much larger than that of the reference drug, safety of the test drug could be

a concern. Thus in addition to comparing mean responses between treatments, it is also of interest to compare the variabilities associated with the responses between treatments. Especially, in bioequivalence trials, the intrasubject (or within-subject) variability, the intersubject (or between-subject) variability, and the total variability become the primary endpoints if a drug company is to establish individual and/or population bioequivalence as well as average bioequivalence.

In the next section, the main idea of the original MLS method will be introduced when all coefficients are positive and estimators of variance components are independent. The extensions of the MLS method for the general cases such that (1) signs of coefficients are unrestricted; (2) setting confidence bound on a ratio of linear combinations of variance components; (3) its extension when estimators are not independent, will be discussed in subsequent sections, respectively. The last section will discuss applications of the MLS method in bioequivalence studies based on the guidances published by the Food and Drug Administration (FDA).

OVERVIEW

Denote the distribution of a random vector $\mathbf{x}$ by $\mathcal{L}(\mathbf{x})$. Hence $\mathcal{L}(\mathbf{x}) = \mathcal{L}(\mathbf{y})$ means that $\mathbf{x}$ and $\mathbf{y}$ have the same distribution. We use $N(\boldsymbol{\mu}, \mathbf{V})$ to denote the normal distribution with mean $\boldsymbol{\mu}$ and covariance matrix $\mathbf{V}$ and use χ_r^2 to denote a random variable having the central chi-square distribution with r degrees of freedom. The α th quantile of $N(0,1)$, $\mathcal{L}(\chi_r^2)$, the central t -distribution with degrees of freedom r , and F -distribution with degrees of freedom r_1, r_2 are denoted by z_α , $\chi_{\alpha,r}^2$, $t_{\alpha,r}$, and F_{α,r_1,r_2} , respectively. Note that α th quantile is the lower α th quantile such as $P(Z \leq z_\alpha) = \alpha$. The transpose of the vector $\mathbf{x}$ is denoted by $\mathbf{x}'$, and the Kronecker product of two matrices, $\mathbf{A}$ and $\mathbf{B}$, is denoted by $\mathbf{A} \otimes \mathbf{B}$.

MAIN IDEA OF MODIFIED LARGE SAMPLE METHOD

Consider the problem of setting a $1 - \alpha$ upper confidence bound for $\eta = c_1\sigma_1^2 + \dots + c_p\sigma_p^2$, where $\sigma_1^2, \dots, \sigma_p^2$ are unknown variance components and $c_1, \dots, c_p$ are known positive constants. Let $\hat{\sigma}_i^2$ be an unbiased estimator of σ_i^2 such that $\mathcal{L}(\hat{\sigma}_i^2) = \mathcal{L}(\sigma_i^2 n_i^{-1} \chi_{n_i}^2)$, $i = 1, \dots, p$. In practice, $\hat{\sigma}_i^2$ is typically a quadratic form of an observed normal random vector (e.g., a sample variance or a mean square error). For any fixed i , an exact $1 - \alpha$ upper confidence bound for σ_i^2 is

$$\frac{n_i}{\chi_{\alpha, n_i}^2} \hat{\sigma}_i^2 = \hat{\sigma}_i^2 + \sqrt{\hat{\sigma}_i^4 \left(\frac{n_i}{\chi_{\alpha, n_i}^2} - 1 \right)^2} \quad (2)$$

However, when $p \geq 2$, an exact upper confidence bound for η usually does not exist.

Suppose that $\hat{\sigma}_1^2, \dots, \hat{\sigma}_p^2$ are independent. Then

$$\begin{aligned} \text{Var}(c_1\hat{\sigma}_1^2 + \dots + c_p\hat{\sigma}_p^2) &= c_1^2 \text{Var}(\hat{\sigma}_1^2) + \dots + c_p^2 \text{Var}(\hat{\sigma}_p^2) \\ &= c_1^2 \sigma_1^4 n_1^{-2} \text{Var}(\chi_{n_1}^2) + \dots + c_p^2 \sigma_p^4 n_p^{-2} \text{Var}(\chi_{n_p}^2) \\ &= c_1^2 \sigma_1^4 2n_1^{-1} + \dots + c_p^2 \sigma_p^4 2n_p^{-1} \end{aligned} \quad (3)$$

An estimator of the variance in Eq. 3 is then obtained by replacing σ_i^4 in Eq. 3 by its estimator $\hat{\sigma}_i^4$. For large n_i 's, these results and the Central Limit Theorem lead to the following approximate $1 - \alpha$ upper confidence bound for η :

$$\begin{aligned} c_1\hat{\sigma}_1^2 + \dots + c_p\hat{\sigma}_p^2 + z_{1-\alpha} \sqrt{c_1^2 \hat{\sigma}_1^4 2n_1^{-1} + \dots + c_p^2 \hat{\sigma}_p^4 2n_p^{-1}} \\ = c_1\hat{\sigma}_1^2 + \dots + c_p\hat{\sigma}_p^2 + \sqrt{c_1^2 \hat{\sigma}_1^4 2z_{1-\alpha}^2 n_1^{-1} + \dots + c_p^2 \hat{\sigma}_p^4 2z_{1-\alpha}^2 n_p^{-1}} \end{aligned} \quad (4)$$

In view of Eq. 2, Graybill and Wang^[2] proposed to replace $2z_{1-\alpha}^2 n_i^{-1}$ in Eq. 4 by $\left(\frac{n_i}{\chi_{\alpha, n_i}^2} - 1 \right)^2$, $i = 1, \dots, p$, and referred this method as the Modified Large Sample (MLS) method. The resulting upper confidence bound for η is then

$$\begin{aligned} c_1\hat{\sigma}_1^2 + \dots + c_p\hat{\sigma}_p^2 \\ + \sqrt{c_1^2 \hat{\sigma}_1^4 \left(\frac{n_1}{\chi_{\alpha, n_1}^2} - 1 \right)^2 + \dots + c_p^2 \hat{\sigma}_p^4 \left(\frac{n_p}{\chi_{\alpha, n_p}^2} - 1 \right)^2} \end{aligned} \quad (5)$$

Using a similar argument, we can obtain the following MLS lower confidence bound for η :

$$\begin{aligned} c_1\hat{\sigma}_1^2 + \dots + c_p\hat{\sigma}_p^2 \\ - \sqrt{c_1^2 \hat{\sigma}_1^4 \left(\frac{n_1}{\chi_{1-\alpha, n_1}^2} - 1 \right)^2 + \dots + c_p^2 \hat{\sigma}_p^4 \left(\frac{n_p}{\chi_{1-\alpha, n_p}^2} - 1 \right)^2} \end{aligned} \quad (6)$$

An equal-tail, two-sided MLS confidence interval for η can be obtained by using the upper bounds (Eq. 5) and the lower bound (Eq. 6) as the interval limits.

The MLS confidence bound has the following properties:

Property 1. The confidence bound in Eq. 5 is asymptotically correct; that is, the coverage probability of the confidence bound converges to $1 - \alpha$ when all n_i 's increase to infinity. This is because

$$\lim_{n \rightarrow \infty} \frac{n}{2} \left(\frac{n}{\chi_{\alpha, n}^2} - 1 \right)^2 = z_{1-\alpha}^2$$

which can be proven using the Cornish–Fisher expansion.

Property 2. When $\sigma_i^2 > 0$ and $\sigma_j^2 = 0$ for all $j \neq i$, the confidence bound in Eq. 5 reduces to the confidence bound in Eq. 2. Hence it is an exact confidence bound. This property is not enjoyed by the confidence bound in Eq. 4.

Property 1 implies that the coverage probability of the MLS confidence bound converge to the intended confidence coefficient $1 - \alpha$ as sample sizes become large. The finite sample evaluation of coverage probability of the MLS confidence bounds were investigated by using the numerical integration in Ref. [2]. The numerical evaluation in Ref. [2] indicates that the MLS method is comparable to the method in Refs. [3,4] and is also conservative in the sense that the finite sample coverage probabilities are larger than $1 - \alpha$ for most cases. Property 2 is the main and unique advantage of the MLS method over other competing methods. When one of the variance components is relatively larger than the others, the MLS method gives an almost exact confidence bound. This property was also discussed by Howe.^[1] Other than these two properties of the MLS method, another good property is its simplicity.

AN EXTENSION OF THE MODIFIED LARGE SAMPLE METHOD TO DIFFERENCE OF VARIANCE COMPONENTS

In this section, we will consider an extension of the MLS method when the signs of coefficient in Eq. 1 are unrestricted. Originally, Howe^[1] considered an approximate confidence bound on intersubject (between-group) variance in one-way classification model by using a similar idea to Graybill and Wang.^[2] First, Howe's idea will be introduced and, second, its generalizations will be discussed.

Consider two mean squares $\hat{\sigma}_1^2$ and $\hat{\sigma}_2^2$, which are distributed independently and

$$\mathcal{L}(\hat{\sigma}_1^2) = \mathcal{L}\left(\frac{(\sigma_a^2 + \sigma_e^2)\chi_{n_1}^2}{n_1}\right), \quad \mathcal{L}(\hat{\sigma}_2^2) = \mathcal{L}\left(\frac{\sigma_e^2 \chi_{n_2}^2}{n_2}\right)$$

Therefore an unbiased estimator of σ_a^2 is given by $\hat{\sigma}_1^2 - \hat{\sigma}_2^2$. For this example, if

$$F = \frac{\hat{\sigma}_1^2}{\hat{\sigma}_2^2} \leq F_{\alpha, n_1, n_2}$$

then the upper confidence bound of σ_a^2 is zero. Howe^[1] considered this as an extra piece of readily available information and incorporated this information with the idea of the MLS method to construct more accurate confidence bound on σ_a^2 . The $1 - \alpha$ MLS upper confidence bound of σ_a^2 can be defined as

$$\hat{\sigma}_1^2 - \hat{\sigma}_2^2 + \sqrt{V}$$

where

$$V = \hat{\sigma}_1^4 \left(\frac{n_1}{\chi_{\alpha, n_1}^2} - 1 \right)^2 + A \hat{\sigma}_2^4 \quad (7)$$

Now the constant A in Eq. 7 can be determined by forcing the upper confidence bound $\hat{\sigma}_1^2 - \hat{\sigma}_2^2 + \sqrt{V}$ to be 0 when $\hat{\sigma}_1^2 / \hat{\sigma}_2^2 = F_{\alpha, n_1, n_2}$. This imposed condition leads to the equation for A . By using the solution for A from the given equation, $1 - \alpha$ MLS upper confidence bound of σ_a^2 is given by

$$\begin{cases} 0 & \text{if } F \leq F_{\alpha, n_1, n_2} \\ \hat{\sigma}_1^2 - \hat{\sigma}_2^2 + \sqrt{V} & \text{if } F > F_{\alpha, n_1, n_2} \end{cases} \quad (8)$$

where $F = \hat{\sigma}_1^2 / \hat{\sigma}_2^2$ and

$$V = \hat{\sigma}_1^4 \left(\frac{n_1}{\chi_{\alpha, n_1}^2} - 1 \right)^2 + \hat{\sigma}_2^4 \left[(F_{\alpha, n_1, n_2} - 1)^2 - F_{\alpha, n_1, n_2}^2 \left(\frac{n_1}{\chi_{\alpha, n_1}^2} - 1 \right)^2 \right]$$

Note that the confidence bound in Eq. 8 is using an extra information such as $\sigma_a^2 > 0$ in the model considered.

Consider a more general parameter $c_1 \sigma_1^2 - c_2 \sigma_2^2$, where c_1 and c_2 are known positive real numbers. However, for this general case, if the parameter $c_1 \sigma_1^2 - c_2 \sigma_2^2$ can be negative, the MLS confidence upper bound in Eq. 8 is no longer valid. For this case, Lu et al.^[5] extended Howe's confidence bound in Eq. 8 as

$$\begin{cases} c_1 \hat{\sigma}_1^2 - c_2 \hat{\sigma}_2^2 + \sqrt{V^*} & \text{if } F \leq F_{\alpha, n_1, n_2} \\ c_1 \hat{\sigma}_1^2 - c_2 \hat{\sigma}_2^2 + \sqrt{V} & \text{if } F > F_{\alpha, n_1, n_2} \end{cases} \quad (9)$$

where F and V are the same as in Eq. 8 except using $c_i \hat{\sigma}_i^2$ instead of $\hat{\sigma}_i^2$ and

$$V^* = c_1^2 \hat{\sigma}_1^4 \left[\left(\frac{1}{F_{\alpha, n_1, n_2}} - 1 \right)^2 - \left(\frac{1}{F_{\alpha, n_1, n_2}} \right)^2 \left(\frac{n_2}{\chi_{1-\alpha, n_2}^2} - 1 \right)^2 \right] + \hat{\sigma}_2^4 \left(\frac{n_2}{\chi_{1-\alpha, n_2}^2} - 1 \right)^2$$

Note that the bound in Eq. 9 is exact when 1) $\sigma_1 = 0$; 2) $\sigma_2 = 0$; 3) $c_1 \sigma_1^2 = c_2 \sigma_2^2$. Furthermore, Ting et al.^[6] considered MLS confidence bounds for more general cases such that the parameter of interest can be described as

$$\sum_{i=1}^q c_i \sigma_i^2 - \sum_{j=q+1}^p c_j \sigma_j^2$$

where $q < p$ and $c_1, \dots, c_p$ are all positive real numbers. Also, the alternative form of the MLS upper confidence bound was proposed by Ting et al.^[6] without considering the F test in Eq. 9, and it can be described as

$$\sum_{i=1}^q c_i \hat{\sigma}_i^2 - \sum_{j=q+1}^p c_j \hat{\sigma}_j^2 + \sqrt{W} \quad (10)$$

where

$$W = \sum_{i=1}^q c_i^2 \hat{\sigma}_i^4 L_i^2 + \sum_{j=q+1}^p c_j^2 \hat{\sigma}_j^4 L_j^2 + \sum_{i=1}^q \sum_{j=q+1}^p c_i c_j \hat{\sigma}_i^2 \hat{\sigma}_j^2 L_{ij}$$

and L_i, L_j, L_{ij} are appropriately chosen to make the MLS upper confidence bound exact for some special cases. Note that we can simplify the confidence bound in Eq. 10 by ignoring the cross-product terms $\sum_{i=1}^q \sum_{j=q+1}^p c_i c_j \hat{\sigma}_i^2 \hat{\sigma}_j^2 L_{ij}$. Moreover, if we consider Property 1 in the previous section as the imposed condition for special cases (i.e., an exact confidence bound when only one variance component is positive and the others are zero), the following simplified $1 - \alpha$ MLS confidence upper bound can be obtained:

$$\sum_{i=1}^q c_i \hat{\sigma}_i^2 - \sum_{j=q+1}^p c_j \hat{\sigma}_j^2 + \sqrt{W^*} \quad (11)$$

where

$$W^* = \sum_{i=1}^q c_i^2 \hat{\sigma}_i^4 L_i^2 + \sum_{j=q+1}^p c_j^2 \hat{\sigma}_j^4 L_j^2$$

and

$$L_i^2 = \left(\frac{n_i}{\chi_{\alpha, n_i}^2} - 1 \right)^2, \quad i = 1, \dots, q;$$

$$L_j^2 = \left(\frac{n_j}{\chi_{1-\alpha, n_j}^2} - 1 \right)^2, \quad j = q+1, \dots, p$$

Note that the form in Eq. 11 is the most simplified form of the MLS confidence bound and it is used for tests of Individual/Population Bioequivalence, which will be discussed in the last section.

AN EXTENSION OF THE MODIFIED LARGE SAMPLE METHOD TO RATIO OF VARIANCE COMPONENTS

In many experimental designs, a certain ratio of variance components becomes the parameter of interest. For example, under one-way random effect model, a ratio of intersubject variance and total variance is often considered as an important parameter, which is called as the heritability measure in genetics. The MLS confidence bound on the ratio of variance components have been extensively developed by Burdick et al.^[7-10] In this section, the MLS confidence bound by Gui et al.^[8] will be introduced.

Consider the problem of setting a confidence upper bound on the ratio

$$\rho = \frac{\sigma_2^2 + \sigma_3^2}{\sigma_1^2 + \sigma_2^2}$$

The $1 - \alpha$ upper bound on the ratio ρ can be defined by U such that $P(\rho < U)$ is close to $1 - \alpha$. Note that $P[\rho < U] = P[(\sigma_2^2 + \sigma_3^2)/(\sigma_1^2 + \sigma_2^2) < U] = P(\gamma_U < 0)$ such that

$$\gamma_U = -U\sigma_1^2 + (1-U)\sigma_2^2 + \sigma_3^2 \quad (12)$$

Because γ_U in Eq. 12 is a linear combination of variance components, the MLS method discussed in the previous section can be applied to find $1 - \alpha$ MLS confidence upper bound on γ_U such as $P(\gamma_U < U^*) \approx 1 - \alpha$. On the other hand, we also desire $P(\gamma_U < 0) \approx 1 - \alpha$. Therefore we have the quadratic equation $U^* = 0$ in terms of U and the solution for U can be considered as $1 - \alpha$ MLS confidence upper bound on the ratio ρ .

However, there is one difficulty in constructing confidence bound on γ_U in Eq. 12 because the sign of U in Eq. 12 cannot be determined prior to setting the bound. For example, if $\sigma_3^2 > \sigma_1^2$, then $\rho > 1$, which, in turn, implies $U > 1$. Therefore we can determine the sign of $1 - U$, which is the coefficient of σ_2^2 in Eq. 12. On the other hand, if $\sigma_3^2 < \sigma_1^2$, then $\rho < 1$. For this case, Gui et al.^[8] recommend to restrict the range of U by $0 < U < 1$. For either case, as discussed in the previous section, we can apply the MLS method by Lu et al.^[5] to construct $1 - \alpha$ MLS confidence upper bound on γ_U and its form is given in Eq. 9. Gui et al.^[8] proposed the procedure to find MLS confidence bound on ρ such that 1) assume $\sigma_3^2 > \sigma_1^2$; 2) compute an upper bound U ; 3) if $U > 1$, then stop; 4) if $U < 1$, then assume $\sigma_3^2 \leq \sigma_1^2$ and find U again.

Gui et al.^[8] considered constructing the MLS confidence bound on a more general parameter such that

$$\rho = \frac{\sum_{i=1}^q c_i \sigma_i^2 - \sum_{j=q+1}^p c_j \sigma_j^2}{\sum_{k=1}^r c_k \sigma_k^2}$$

The explicit form of confidence interval and more details can be found in Ref. [8].

AN EXTENSION OF THE MODIFIED LARGE SAMPLE METHOD WHEN ESTIMATORS ARE DEPENDENT

One of the important assumptions for the MLS method is that estimators of variance components should be independent. However, in practice, this independent assumption might not be satisfied. For example, if we consider a linear combination of variance components in the multivariate normal distribution, the sample variances are not independent. Furthermore, in replicated crossover design, the estimators of intersubject variability (or total variability) between two treatments are not independent.

Note that when $\hat{\sigma}_1^2, \dots, \hat{\sigma}_p^2$ are dependent, result Eq. 3 does not hold and, consequently, Eqs. 4–6 are asymptotically incorrect; that is, their coverage probabilities do not converge to the nominal level $1 - \alpha$, although confidence bounds Eqs. 5 and 6 still enjoy Property 2 in the “Main Idea of Modified Large Sample Method” section. Lee^[11] considered the extension of the MLS method when estimators are dependent. We will consider a main idea of the extension of the MLS method and present an example with multivariate normal distribution to illustrate an application of the extension.

Assume that $\hat{\sigma}_i^2$'s are quadratic forms of an observed normal random vector and c_i 's are known nonzero real numbers. Our extension builds on the fact that the quadratic form $c_1 \hat{\sigma}_1^2 + \dots + c_p \hat{\sigma}_p^2$ may have a *chi-square representation* in the sense that

$$\mathcal{L}(c_1 \hat{\sigma}_1^2 + \dots + c_p \hat{\sigma}_p^2) = \mathcal{L}(\lambda_1 n_1^{-1} \chi_{n_1}^2 + \dots + \lambda_q n_q^{-1} \chi_{n_q}^2) \quad (13)$$

where $\chi_{n_1}^2, \dots, \chi_{n_q}^2$ are independent chi-square random variables and λ_i 's are unknown parameters that are function of variance components and coefficients c_i 's. Also, assume that the signs of λ_i 's are known. However, in each application, one has to derive the explicit form of the chi-square representation. When $\hat{\sigma}_1^2, \dots, \hat{\sigma}_p^2$ are independent, Eq. (13) holds with $\lambda_i = c_i \sigma_i^2$.

Although the chi-square random variables $\chi_{n_1}^2, \dots, \chi_{n_q}^2$ in Eq. (13) are not observable, the coefficients $\lambda_1, \dots, \lambda_q$ usually have consistent estimators that can be obtained from observed sample. Using Eq. 13 and applying the argument by Lu et al.^[5] to the independent linear combination

$\lambda_1 n_1^{-1} \chi_{n_1}^2 + \dots + n_q^{-1} \lambda_q \chi_{n_q}^2$, we obtain the following extended MLS upper and lower confidence bounds:

$$c_1 \hat{\sigma}_1^2 + \dots + c_p \hat{\sigma}_p^2 + \sqrt{\hat{\lambda}_1^2 \left(\frac{n_1}{u_1} - 1 \right)^2 + \dots + \hat{\lambda}_q^2 \left(\frac{n_q}{u_q} - 1 \right)^2} \quad (14)$$

and

$$c_1 \hat{\sigma}_1^2 + \dots + c_p \hat{\sigma}_p^2 - \sqrt{\hat{\lambda}_1^2 \left(\frac{n_1}{l_1} - 1 \right)^2 + \dots + \hat{\lambda}_q^2 \left(\frac{n_q}{l_q} - 1 \right)^2} \quad (15)$$

where $\hat{\lambda}_i$ is a consistent estimator of λ_i , $i = 1, \dots, q$,

$$u_i = \begin{cases} \chi_{\alpha, n_i}^2 & \lambda_i > 0 \\ \chi_{1-\alpha, n_i}^2 & \lambda_i < 0 \end{cases} \quad \text{and} \quad (16)$$

$$l_i = \begin{cases} \chi_{\alpha, n_i}^2 & \lambda_i < 0 \\ \chi_{1-\alpha, n_i}^2 & \lambda_i > 0 \end{cases}$$

Note that, when $\hat{\sigma}_1^2, \dots, \hat{\sigma}_p^2$ are independent, $\hat{\lambda}_i = c_i \hat{\sigma}_i^2$. The extended MLS confidence bounds Eq. 14 and Eq. 15 enjoy Properties 1 and 2 of the original MLS method.

Because most of the estimators of variance components under the normal assumption can be described as a quadratic form of multivariate normal distribution, we will consider multivariate normal distribution to illustrate an idea of extension of the MLS method. Let $\mathbf{y}_1, \dots, \mathbf{y}_n$ be independent and identically distributed p -dimensional random vectors with $\mathcal{L}(\mathbf{y}_i) = N(\mu, \mathbf{V})$. Suppose that the parameter η is a linear combination of the p diagonal elements of $\mathbf{V}$ such that $\eta = c_1 \sigma_1^2 + \dots + c_p \sigma_p^2$. Let be the sample covariance matrix and $\hat{\sigma}_i^2$ be its i th diagonal element. Note that $\hat{\sigma}_1^2, \dots, \hat{\sigma}_p^2$ are dependent unless $\mathbf{V}$ is diagonal. Define $\mathbf{y} = (\mathbf{y}_1', \dots, \mathbf{y}_n')'$. Then, a linear combination of estimators of variance components can be described as a quadratic form such that

$$c_1 \hat{\sigma}_1^2 + \dots + c_p \hat{\sigma}_p^2 = \mathbf{y}' \mathbf{A} \mathbf{y}$$

is a quadratic form, where

$$\mathbf{A} = \mathbf{C} \otimes \mathbf{J}_n, \quad \mathbf{J}_n = (n-1)^{-1} (\mathbf{I}_n - n^{-1} \mathbf{1}_n \mathbf{1}_n')$$

$\mathbf{I}_n$ is the identity matrix of order n , $\mathbf{1}_n$ is the n -dimensional vector of 1's, and $\mathbf{C}$ is a diagonal matrix whose i th diagonal element is c_i . Note that $\mathcal{L}(\mathbf{y}) = N(\tilde{\mu}, \tilde{\mathbf{V}})$, where $\tilde{\mu} = \mu \otimes \mathbf{1}_n$ and $\tilde{\mathbf{V}} = \mathbf{V} \otimes \mathbf{I}_n$. The distribution of quadratic form $\mathbf{y}' \mathbf{A} \mathbf{y}$ is not straightforward, but it can be shown that the distribution of this quadratic form is equivalent to that of a linear combination of independent chi-square random variables by using the moment generating function of $\mathbf{y}' \mathbf{A} \mathbf{y}$. The moment generating function of $\mathbf{y}' \mathbf{A} \mathbf{y}$ is given by

$$E[\exp(t \mathbf{y}' \mathbf{A} \mathbf{y})] = \left(1 - \frac{2t\lambda_1}{n-1}\right)^{-\frac{n-1}{2}} \dots \left(1 - \frac{2t\lambda_p}{n-1}\right)^{-\frac{n-1}{2}}$$

where $\lambda_1, \dots, \lambda_p$ are the roots of the equation

$$|\lambda \mathbf{I}_p - \mathbf{C} \mathbf{V}| = |\lambda \mathbf{V}^{-1} - \mathbf{C}| = 0 \quad (17)$$

i.e., $\lambda_1, \dots, \lambda_p$ are the eigenvalues of $\mathbf{C} \mathbf{V}$.

Hence the moment generating function of the quadratic form $\mathbf{y}' \mathbf{A} \mathbf{y}$ is same as that of a linear combination of independent chi-square random variable so that the quadratic form has chi-square representation such as

$$\mathcal{L}(\mathbf{y}' \mathbf{A} \mathbf{y}) = \mathcal{L}(\lambda_1 (n-1)^{-1} \chi_{n-1,1}^2 + \dots + \lambda_p (n-1)^{-1} \chi_{n-1,p}^2)$$

where $\chi_{n-1,i}^2$, $i = 1, \dots, p$ are independent chi-square random variables with $n-1$ degrees of freedom. This means that $c_1 \hat{\sigma}_1^2 + \dots + c_p \hat{\sigma}_p^2 = \mathbf{y}' \mathbf{A} \mathbf{y}$ has the chi-square representation (Eq. 13) with $n_i = n-1$ and λ_i 's as the solutions of Eq. 17. Let $\hat{\lambda}_1, \dots, \hat{\lambda}_p$ be the solution of Eq. 17 with $\mathbf{V}$ replaced by, which is any consistent estimator of $\mathbf{V}$. Then $\hat{\lambda}_i$ is a consistent estimator of λ_i as $n \rightarrow \infty$ and the extended MLS confidence bounds Eq. 14 and Eq. 15 can be obtained.

We will consider the bivariate normal distribution with simulation studies for further illustration. The covariance matrix $\mathbf{V}$, its estimator $\hat{\mathbf{V}}$, and the coefficient matrix $\mathbf{C}$ are given by

$$\mathbf{V} = \begin{pmatrix} \sigma_1^2 & \rho \sigma_1 \sigma_2 \\ \rho \sigma_1 \sigma_2 & \sigma_2^2 \end{pmatrix}, \quad \hat{\mathbf{V}} = \begin{pmatrix} \hat{\sigma}_1^2 & \hat{\sigma}_{12} \\ \hat{\sigma}_{21} & \hat{\sigma}_2^2 \end{pmatrix},$$

$$\mathbf{C} = \begin{pmatrix} c_1 & 0 \\ 0 & c_2 \end{pmatrix}$$

Note that $\eta = c_1 \sigma_1^2 + c_2 \sigma_2^2$, which is estimated by $c_1 \hat{\sigma}_1^2 + c_2 \hat{\sigma}_2^2$. Without loss of generality, let $\lambda_1 = \lambda_-$ and $\lambda_2 = \lambda_+$ be the eigenvalues of $\mathbf{C} \mathbf{V}$, i.e.

$$\lambda_{\pm} = \frac{c_1 \sigma_1^2 + c_2 \sigma_2^2 \pm \sqrt{(c_1 \sigma_1^2 - c_2 \sigma_2^2)^2 + 4 c_1 c_2 \rho^2 \sigma_1^2 \sigma_2^2}}{2} \quad (18)$$

Estimators $\hat{\lambda}_1$ and $\hat{\lambda}_2$ can be obtained by replacing σ_i^2 and $\rho \sigma_1 \sigma_2$ in the previous equation by the corresponding estimators $\hat{\sigma}_i^2$ and $\hat{\sigma}_{12}$, respectively.

APPLICATION OF THE MODIFIED LARGE SAMPLE METHOD TO BIOEQUIVALENCE STUDIES

Bioequivalence between two different formulations of a drug product is established when the two formulations have equivalent bioavailability. Bioavailability is described

as the rate and extent that a drug in some dosage form is absorbed and becomes available at the site of the pharmacological effect. Pharmacokinetic (PK) response such as the area under the concentration time curve (AUC) or the maximum concentration ($C_{\max}$) is usually considered as measures of bioavailability.^[12–16]

The recent FDA guidance^[16] describes average bioequivalence (ABE), individual bioequivalence (IBE), and population bioequivalence (PBE) for establishment of bioequivalence between a test formulation and a reference formulation. Average bioequivalence can be claimed if the 90% confidence interval of the ratio of population means between the test formulation and the reference formulation falls within 80% and 125%. However, ABE has limitations because it only focuses on the average of bioavailability, and ignores the variability of bioavailability when assessing bioequivalence. As a result, it does not guarantee drug interchangeability. Drug *interchangeability* include the concepts of drug *switchability* and *prescribability*. Drug switchability can be established if a patient who receives the reference formulation can expect similar bioavailability when switches in the test formulation occur. The FDA recommends IBE be used to assess drug switchability. Individual bioequivalence takes into consideration of within-subject variability and variability due to subject by formulation interaction. Drug prescribability can be claimed if the distribution of PK responses to the reference formulation is sufficiently similar to the distribution of PK responses to the test formulation. The FDA suggests PBE be used to assess drug prescribability. Population bioequivalence includes comparison of total variabilities between formulations. Hence if PBE is claimed, the physician can prescribe one of two formulations to the patient with the same expectation for the therapeutic effect.

The measures for IBE and PBE are described in the guidance.^[16] Let y_T be the log-transformed PK response of a subject that is treated by the test formulation, and y_R, y_R^* be two identically distributed log-transformed PK responses to the reference formulation. Motivated by Schall and Luus,^[17] the FDA^[16] defines a measure of PBE by the quantity

$$\theta = \begin{cases} \frac{E(y_R - y_T)^2 - E(y_R - y_R^*)^2}{E(y_R - y_R^*)^2/2} & \text{if } E(y_R - y_R^*)^2/2 \geq \sigma_0^2 \\ \frac{E(y_R - y_T)^2 - E(y_R - y_R^*)^2}{\sigma_0^2} & \text{if } E(y_R - y_R^*)^2/2 < \sigma_0^2 \end{cases} \quad (19)$$

where σ_0^2 is a constant specified by the FDA.

Assume that y_T, y_R , and y_R^* in Eq. 19 are from the same subject. Then, IBE can be claimed if the following null hypothesis H_0 is rejected at the 5% level of significance:

$$H_0: \theta \geq \theta_l \quad \text{vs.} \quad H_1: \theta < \theta_l \quad (20)$$

where θ_l is an upper limit specified by the FDA. Note that if y_T, y_R , and y_R^* in Eq. 19 are independent observations from different subjects, θ becomes the measure to establish PBE. In Ref. [16] 2×4 crossover design is recommended to assess the measure of PBE and IBE.

Hyslop et al.^[18] propose a statistical test for IBE by using the MLS method after the original hypothesis (Eq. 20) is transformed to an equivalent hypothesis in which new parameter can be written as a linear combination of variance components. The FDA^[16] adopted the statistical test for IBE by Hyslop et al.^[18] and applied the same argument to construct a statistical test for PBE. Alternatively, Quiroz et al.^[19,20] proposed tests to assess IBE and PBE by applying the MLS confidence upper bound on the original ratio criteria in Eq. 19. The FDA's tests for IBE/PBE are simpler than those by Quiroz, but the FDA's test for PBE is conservative so that it gives very low power in some situations. The test for PBE by Quiroz et al.^[20] is better than the FDA's test in terms of its size, which is more closer than nominal level 0.05 than the FDA's test.

The key assumption for the original MLS method is that estimators of variance components should be independent. However, it is shown by Chow et al.^[21] that the estimators of the variance components in the test for PBE by the FDA^[16] are not independent so that the asymptotic size of the test is always strictly less than the nominal level except for some special cases. This implies that the FDA test is too conservative and gives unnecessarily low powers. By using normal approximation, Chow et al.^[21] proposed an asymptotic test that gives the correct asymptotic size. Lee^[11] proposed a test for PBE by using the extended MLS, which can be applied to the case when estimators are dependent. The test based on the extended MLS method has more power than the FDA's test for PBE and its size is very close the nominal level. Furthermore, Lee et al.^[22] showed that the extended MLS method can be used to compare intersubject and total variability under replicate crossover designs.

For locally acting drug product such as nasal aerosol and nasal spray, which are not intended to be absorbed into the bloodstream, bioavailability and the corresponding bioequivalence can be assessed in in vitro studies alone.^[23,24] Statistical methods for assessment of in vitro bioequivalence testing for locally acting drug can be classified into two categories: the nonprofile analysis and the profile analysis. The FDA^[23] used the same criteria as that for PBE and applied the MLS method to construct a test for the nonprofile analysis. Note that the experimental design for the nonprofile analysis is a parallel design so that estimators of variance components are independent, which implies that the original MLS method can be applied without consideration about dependency among estimators.

CONCLUSION

The MLS method is useful in providing statistical inference for any linear combination of variance components of the form:

$$c_1\sigma_1^2 + c_2\sigma_2^2 + \cdots + c_p\sigma_p^2$$

Its applications in biopharmaceutical research include the assessment of in vivo bioequivalence (i.e., IBE and PBE) and in vitro bioequivalence. In recent years, the assessment of reproducibility in clinical research has attracted much attention. The concept of the MLS method can be applied for obtaining statistical inference on reproducibility of study endpoints of interest in clinical research as well.

Multicenter Trials

William J. Huster

Eli Lilly and Company, Indianapolis, Indiana, U.S.A.

Abstract

A multicenter clinical trial is a clinical trial involving more than one clinical center that is conducted to evaluate the effectiveness of a therapeutic agent according to a common protocol. This entry reviews the statistical design and analysis involved with multicenter trials and discusses the regulatory requirements for these trials.

INTRODUCTION

A multicenter clinical trial is a clinical trial (see *Clinical Trials* entry) involving more than one clinical center (i.e., study site, investigator, field site, clinic) that is conducted to evaluate the effectiveness of a therapeutic agent according to a common protocol. Multicenter trials have been utilized in clinical medicine since the 1940s, as documented by Bradford Hill^[1] in his seminal work on the statistical aspects of trials of antihistamines, cortisone, and streptomycin. Multicenter trials are employed primarily for two reasons: (1) the use of multiple centers allows adequate and/or rapid accrual of patients, and (2) the involvement of multiple centers enhances the generalizability of the results because of the anticipated heterogeneity in patient populations and center practices. This latter rationale is attractive because it more closely resembles how the therapeutic agent will be utilized when commercially available. Other reasons for utilizing multicenter trials are to introduce state-of-the-art therapies to the medical community as well as to solicit a wider range of clinical opinions concerning the utility of therapeutic agent.

OVERVIEW

Many of the aspects of multicenter trials run by the pharmaceutical industry are similar to those of multicenter trials run by collaborative efforts sponsored by government agencies (e.g., National Institutes of Health). However, there are several important differences. Pharmaceutical industry trials evaluate new therapeutic agents for regulatory approval in a specific patient population. Often, these multicenter trials are used in phase 3 of drug development (see *Drug Development* entry), sometimes as the pivotal studies in the new drug application to the Food and Drug Administration (see *Food and Drug Administration* entry). Collaborative trials address outstanding medical questions for approved therapeutic agents in a broader patient population; the results of these trials profoundly affect current medical

practice.^[2] In addition, because pharmaceutical industry trials evaluate new therapeutic agents, there is a need for timely safety monitoring and periodic safety reporting to regulatory agencies during the trial. Collaborative trials are not subject to such regulatory oversight, because they evaluate approved therapeutic agents about which the safety profile is known. See “Multicenter Trials” in the *Encyclopedia of Biostatistics*^[3] for a more complete description of collaborative multicenter trials. The following discusses aspects of multicenter trials in the pharmaceutical industry.

By its nature, a multicenter clinical trial is organizationally complex, requiring careful protocol development (see *Protocol Development* entry) and implementation as well as clear organizational structure and decision making.

Protocol Development and Implementation

The protocol should be clearly written so that it can be easily understood and uniformly implemented across clinical centers. In particular, entry and therapy/patient discontinuation criteria should be rigorously standardized using verifiable decision rules. The pharmaceutical company (i.e., drug sponsor) should hold investigator meetings and training sessions for study coordinators to assure common understanding of evaluation procedures, especially for the efficacy endpoint (see entries on *Clinical Endpoint* and *Surrogate Endpoint*). Manuals of standard operating procedures should be created to enhance uniformity and protocol adherence further. Ongoing monitoring by the sponsor of each clinical center’s compliance to the protocol should occur throughout the trial. The foregoing concerns are critically important to the success of the study.

Many of the data-collection and data-management issues associated with multicenter trials are similar to those associated with single-center clinical trials. For example, the data collection tool should be designed to collect essential data in a consistent manner. Also, there should be a quality control process in place to ensure that the collected data match the patient’s medical records.

Several new data-management issues are introduced by multicenter trials compared to a single-center trials. For example, a central resource center can be used to perform the evaluation of important objective safety and efficacy endpoints as well as entry criteria. Use of a central resource center ensures standardized, blinded review of these critical data. The logistics of sample collection and flow from the clinical centers to the central resource centers (e.g., collection of blood sent for evaluation to a central laboratory) and the subsequent transfer of the data to the data-management center should be clearly spelled out, facilitated, and monitored by the sponsor.

It is the sponsor's responsibility to have in place a process for monitoring the study for emerging safety issues and for communicating any issues in a timely manner to the regulatory agencies and, if necessary, to the clinical investigators.

Organizational Structure and Decision Making

The organizational structure of and decision-making process for the multicenter trial should be determined and agreed to prior to study initiation. In particular, the roles and responsibilities of each committee should be defined. Usually, there is a study chair (e.g., the principle investigator) and a committee of investigators. The sponsor facilitates communication between investigators by conducting investigator meetings as well as frequent mailings. It is often the role of the investigator committee, in consultation with the sponsor, to plan publications and to resolve authorship.

The study coordinating center is responsible for managing the clinical centers (e.g., monitoring patient accrual, ensuring protocol compliance) and the data-coordinating center is responsible for managing the data and analysis. These coordinating centers may be a contracted research organization (see entry on *Contract Research Organization (CRO)*), an academic center, or medical/data-management/statistical personnel of the sponsor. Also, as already mentioned, there may be several additional resource centers, such as central laboratories and evaluation centers, which are usually external to the sponsor so as to maintain perceived integrity of the results.

Often, Data Safety Monitoring Boards (see also entry on *Data Monitoring Committees (DMC)*) are used to monitor accumulating safety data. In addition, the DSMB may perform an interim analysis (see entry on *Interim Analysis*) of efficacy endpoints, if specified in the protocol. The membership and operation of the DSMBs are kept separate from the study coordinating center so as to minimize risks to study integrity.^[4]

REGULATORY REQUIREMENTS

There are no specific regulatory requirements beyond those noted for clinical trials.^[5]

STATISTICAL DESIGN AND ANALYSIS

Statistical Design

One drawback to the use of multicenter trials is the presence of additional sources of variability which are not present in single-center trials. In particular, a major source of variability is the clinical center. Clinical centers often vary on factors that may be related to either the therapy or clinical endpoint: characteristics of the patients enrolled at the center, specific interests/skills of the center and physician (e.g., family practice vs. referral center), and implementation of the protocol (e.g., how the physician evaluates the patient).^[6] To minimize this variability, the design of multicenter trials usually considers the clinical center as a block. Prospective stratification by clinical center with randomization is generally preferred to achieve balance among therapy groups. However, there are occasions where stratification is not possible or is not necessary. For example, in mortality or cancer trials (see entry on *Cancer Trials*), there may be many centers, each with very few patients, precluding stratification by center. Also, other factors may be felt to be more predictive of the clinical outcome than clinical center. In these cases, randomization may be performed using a stratification scheme administered by a central system (e.g., interactive voice randomization system—see entry on *Interactive Voice Randomization System (IVRS)*) that stratifies on other important factors besides center.^[7]

One should consider the number of centers and the number of patients allocated per center in the design. The guidance from the International Conference on Harmonization (see entry on *International Conference on Harmonization (ICH)*) on Statistical Principles for Clinical Trials^[8] recommends that one should try to avoid excessive variation in the number of patients per center and to avoid centers with very few patients. Such variation, if present, complicates the interpretation of the therapy-by-center interaction (to be discussed in the section “Statistical Analysis”).

The sample size determination (see entry on *Sample Size Determination*) should be specified in the protocol with enough details so that an independent reviewer (e.g., regulatory reviewer) can verify the calculations. The sample size estimated should take into account the design of the trial (e.g., comparative vs. equivalence, parallel vs. crossover), anticipated noncompliance, possibly varying hazards, and the multicenter nature of the study (i.e., the variability may be larger than that seen in single-center trials).^[9] Centralized readings of objective safety and efficacy endpoints may allow a reduction in variability. Sample size and power calculations for the multicenter trial are based on the assumption that the therapy differences from each center are estimating the same quantity. Often, clinical trials are not designed to consider the presence of therapy-by-center interaction,^[10] leaving it to the statistical analysis to explore the robustness of the results to this assumption.

Statistical Analysis

The statistical model for the analysis should be specified in the protocol. If the trial has been stratified on center, this effect should be included in the model to account for variability associated with center as well as to ensure that the appropriate error term is used.^[11] It is generally accepted in the pharmaceutical industry that center is a fixed effect (V.A. Uthoff, personal communication, 1986). This assumption limits the generalizability of the trial results to the centers employed in the trial. Alternatively, the center effect could be considered a random effect so that inference can be more generalizable. However, random-effects models often require greater sample sizes because of the reduced degrees of freedom in the error term. In addition, there is concern that centers do not represent a random sampling of all investigative centers but, rather, are selected on the basis of past performance and the current set of entry criteria.

The protocol should state a priori how therapy-by-center interaction is to be evaluated. In particular, the protocol should state the level of significance to use, whether interaction will be evaluated for all safety and efficacy measures, and time points, how to pool centers with few patients, and what will be carried out if interaction occurs.

If therapy-by-center interaction is not significant, the protocol should specify how interference is to be carried out; e.g., will the full or the reduced model be used? The reduced model is a parsimonious model having greater power for the detection of therapy effects, whereas the full model provides unbiased estimates (i.e., one can never be sure that the interactions really zero). In the latter case, there is controversy whether sequential or partial sums of squares should be used for inference.^[12] The choice ultimately depends on the hypothesis to be tested.

If the therapy-by-center interaction is significant, the interpretation of the main effect is controversial. As already mentioned, a critical assumption for multicenter trials is that the therapy effect is consistent from center to center. When this is not valid, the nature of the interaction should be explored in an attempt to characterize it. Generally, there are two types of interaction: quantitative and qualitative.^[13] *Quantitative* interaction refers to therapy differences that are in the same direction but vary in magnitude across the centers; *qualitative* interaction refers to therapy differences that vary in direction across the centers. Graphical presentation of the therapy effect for each center, as well as identification of the centers having the greatest statistical contribution to the interaction,^[14] is useful to gain insight into the cause of the interaction.

SCIENTIFIC ISSUES

One rationale for the use of multicenter trials is increased heterogeneity in patients and centers, enhancing the generalizability of the trial conclusions. However, there is a

cost associated with multicenter trials. Greater heterogeneity can imply greater variability, leading to compromised power and larger sample sizes for the detection of therapy effects. This increased variability may be reduced through the use of a central reading of objective endpoints.

It is often difficult to define *center*. Is it the region, which may have several investigative centers, is it the hospital/practice, which may have several investigators, or is it the investigator? The driving principle is to define *center* in such a way that one achieves homogeneity in the important factors that affect the outcome variable and therapy.

RECENT DEVELOPMENTS

As mentioned in the statistical design section, there are vague notions concerning the optimal number of centers and number of patients per center as well as concerning the effect of differential sample sizes among centers on the analysis. Shao and Chow^[15] design a multicenter trial using a two-stage sampling plan normally used for United States Pharmacopeia (USP) tests (see entry on *USP Tests*). They show that this plan is optimal in minimizing the variance of the associated statistical testing procedures. Using this sampling plan, one can select the number of centers and number of patients per center to maintain the optimality criterion. Salsburg (1991, personal communication) addresses the issue of minimum sample size per center from the standpoint of the power of the tests for interaction in a two-way fixed-effects analysis of variance (ANOVA). He concludes that, when there is no therapy-by-center interaction or when therapy allocations are balanced within center, differential sample sizes among centers have no effect on alpha level power for hypothesis tests.

A recent work^[16] considers an alternative to sequential or partial sums of squares for inference. Ciminera et al. propose weighting of the therapy effect from each center, depending on the variability observed within each center. Centers are grouped by the observed variability, and more variable centers are given less weight, and vice versa. The authors show that this procedure provides a reasonable estimate of the therapy effect in the presence of heteroskedasticity and “modest” therapy-by-center interaction.

CONCLUSION

Nonparametric statistical tests (specifically, extended Mantel–Haenszel tests) for analyzing data from multicenter trials have proliferated in recent years. Simulation studies have shown that these tests have excellent performance, even under optimal conditions for normal-theory tests.^[17]

In an attempt to bring speed and uniformity to the drug decision-making process, Enas et al.^[18] present a collection of standard statistical and graphical techniques for analyzing multicenter clinical trials. These techniques, easily

automated, facilitate better understanding of the efficacy findings. In addition, strategies evaluating the robustness of inference to varying assumptions are also presented. These strategies are consistent with the use of sensitivity analysis to evaluate robustness as promulgated by Jones.^[19]

The FDA Guidelines for the Clinical and Statistical Sections of New Drug Applications (NDA)^[20] state that the approval of a new therapeutic agent should be “supported by more than one well-controlled trial. ... This interpretation is consistent with the general scientific demand for replicability.” However, when a multicenter trial is viewed as a collection of single-center trials using a common protocol, replication of the therapy effect within the multicenter trial is feasible. Huster and Louv^[21] present a min-max statistic that assesses whether the therapy effect has been replicated in a multicenter trial. They describe the operating characteristics of this statistic under the null and several alternative hypotheses. They also observe that, as described by Salsburg earlier, the power for the detection of a therapy effect is not affected by different sample sizes.

Abstract

This entry summarizes some of the important issues in detecting multicollinearity problems, assessing its severity and locating causal determinants.

Keywords: Diagnostics; High-throughput data; Many predictor variables; Multicollinearity; Remedial measures.

INTRODUCTION

The high throughput of data arising from microarrays, or the complete sequence of the human genome has left scientists with a rich and extensive information source. Moreover, the wide availability of software and the increase in computer power have improved the possibility to access and process, not only genomic data, but also data from many other fields. Therefore it is not surprising that an increasing number of studies involve the simultaneous evaluation of a large pool of predictors (prognostic or risk factors). It is well known that with multiple factors being considered, analyses may be complicated by a multitude of problems. These include investigating many interactions from the same data set and an elevated possibility of finding associations because of chance alone, or “multicollinearity,” among others. In this paper, we summarize some of the important issues in detecting multicollinearity problems, assessing its severity and locating causal determinants.

TWO DISTINCT SETTINGS WHERE MULTICOLLINEARITY MATTERS

Prognostic Factor Analysis Using Quality of Life (QOL) Measures

When evaluating the efficacy of medical treatment on cancer, prolongation of life expectancy and tumor shrinkage have traditionally been taken as outcome measures. Despite the substantial side effects and functional impairment often associated with cancer treatment, it is only recently that attention has been given to the assessment of QOL. Since

the advent of methods for measuring the QOL of patients with cancer, several studies have been published in which QOL variables derived from visual analogue scales and patient-completed questionnaires have been identified as important prognostic factors, in addition to clinical factors.^[1] This finding has considerable importance, particularly in advanced disease where treatment is generally palliative and the aim is to optimize QOL. However, our knowledge of the structure of QOL questionnaires alerted us to difficulties leading to incorrect model selection or ambiguities in determining the direction or magnitude of effects of the predictor variable on the response variable, even with a correct model specification (e.g., Refs. [1] and [2].) It is self-evident that these issues need to be addressed before drawing conclusions from a prognostic factor analysis.

Prognostic factor analysis is widely used in oncology to identify variables that are “independent” predictors of survival and response to treatment. Prognostic factors are used to stratify patients in the design and analysis of clinical trials, to assist in the interpretation of the data generated by such trials, and to aid in the clinical management of individual patients. In the last decade, many methods for measuring QOL have been developed, but in the clinical trial setting, multidimensional patient-completed questionnaires are most widely used. Of these, the EORTC Quality of Life Questionnaire QLQ-C30 is one of the best-known and validated questionnaires, and is available in many languages.^[2] It is a 30-item questionnaire that consists of subscales measuring aspects of function (physical, role, cognitive, emotional, and social), symptoms (pain, dyspnea, nausea/vomiting, loss of appetite, constipation, diarrhea, insomnia, and fatigue), the financial impact of illness and treatment, and overall health and QOL. The last two items

(overall health and QOL) are combined to form the global QOL subscale. This global measure is frequently reported in prognostic factor analyses because of its apparent simplicity and utility as an overall indicator or summary of the patients' QOL. However, it has been known since the first validation study of the QLQ-C30 that the subscales are highly correlated.^[2] This is confirmed by the ordinal measures for correlatedness listed in Table 1.^[3] These findings are to be expected because the questionnaire was specifically designed to measure various components of "QOL." Unfortunately, the impact of correlation between subscales on the outcome of prognostic factor analyses incorporating QOL variables is not always acknowledged in analyses.

Genetic Association Studies and Epistasis

The Human Genome Project, having generated a complete sequence of the human genome in April 2003^[4] and its spinoffs such as the International SNP Map Working Group (Ref. [5]; single nucleotide polymorphism, or SNP), the Allele Frequency/Genotype Project, determining the frequency of 60,000 SNPs in three major world populations, the Genomes to Life Program,^[6] or the Copy Number Variation (CNV) Project,^[7-9] are making it increasingly possible to disentangle the genetic basis of a given disease using genome-wide association studies. The contribution of Copy Number Variants (CNVs) to common complex diseases is largely unknown, but it is suspected that their role in disease etiology may be considerable. The CNV-expression association is complex, in that gene expression levels do not necessarily increase with copy number. CNVs

may be in linkage disequilibrium (LD) with different regulatory variants in different populations or may interact with other CNVs or SNPs.^[10] SNPs are the most common type of genetic variation in humans. They have a dense distribution across the genome (on average about every 1000 base pairs) and a low mutation rate, which makes them ideal markers in genetic association studies. Application of these markers in association analysis is based on the principle that tight linkage can generate allelic association at the population level, provided that most of the disease-bearing chromosomes in the population are descended from one or a few ancestral chromosomes. A popular design, whether SNPs or CNVs are involved as genetic markers, uses cases and controls.^[11]

In a classic logistic modeling framework (case-control status is taken as outcome variable), the search for functional variants can be carried out by constructing a model for the probability of disease (e.g., including only main effects at all variants under investigation). Quantifying the effects of a single locus is achieved by interpreting the corresponding regression coefficients, conditional on the fixed status at the remaining loci. However, if the single locus is involved in a complex multicollinearity pattern with other loci included in the model, it is questionable how much value can be placed on this interpretation. In addition, an increasing number of examples become available in which it is shown that accounting for interaction can lead to improved power to locate disease genes^[12]. In addition, the main effect of a locus may be virtually undetectable because the partner locus has an opposite or reciprocal effect.^[13] These settings point toward the necessity

Table 1 Multicollinearity Tests Based on Chi-Square (Overall Test), *F* (Single Variable), or *t* (Pairs of Variables) Statistics, as Explained in Theil

Test Overall test	Value 606.359 Variable names											
	DY	PF	RF	EF	CF	SF	QL	FA	NV	PA	SL	AP
Single variable	5.801	13.713	13.735	4.393	4.276	10.969	16.830	15.051	7.087	6.094	2.429	7.731

											0	0.180
												0

No *p* values are reported because variables are dichotomous. Therefore the multivariate normal assumption is violated and it makes little sense to rely on distributional properties of the test statistics.

DY = dyspnea, PF = physical functioning, RF = role functioning, EF = emotional functioning, CF = cognitive functioning, SF = social functioning, QL = global quality of life, FA = fatigue, NV = nausea/vomiting, PA = pain, SL = insomnia, and AP = appetite loss.

(From Ref. 16).

to accommodate interactions, hereby drastically increasing the number of parameters in the model. Although Clayton and Jones^[14] argue that higher-order associations fall away at progressively more rapid rates than first-order associations, even the inclusion of only main effects and all two-way interactions might introduce a severe problem of multicollinearity.

Multicollinearity: What is in a Name?

There does not seem to exist a precise operating definition of “multicollinearity.”^[15] Far too often, the term is used for “harmful” multicollinearity and is described in terms of symptoms it might bring about. The symptomatic descriptive view on multicollinearity of Kotz and Johnson^[16] is only one out of many such “definitions” that have passed in review during history. It refers to multicollinearity as “the situation which arises when some of all of the explanatory variables are so highly correlated one with another that it becomes very difficult, if not impossible, to disentangle their influences and obtain a reasonably precise estimate of their separate effects.” Clearly, symptomatic definitions like these have some flaws. In general, they do not offer a full coverage of potentially harmful effects, nor do they give a general setting where problems of multicollinearity can occur. For instance, in the description above, high correlations are sufficient but not necessary for multicollinearity problems to arise.

The underlying mathematical definition for “multicollinearity” is quite simple though: k predictors are collinear if the vectors that represent them lie in a subspace of dimension less than k . In this definition, the sample or observation space is used as a data representation platform. Here, every point in space refers to a predictor or variate. The n axes refer to the items or individuals in the study on which information was collected. This alternative way of representing data is quite convenient to give geometric interpretations to sampled data in terms of lengths, projections, and angles.^[17] It differs from the more classical covariate space, in which every point in space indicates an item or individual and the p axes refer to the measured variates.

The mathematical definition of multicollinearity (“perfect” multicollinearity) rarely applies to practical settings. The linear dependency requirement is not necessary for a collinearity problem to exist; therefore a broader notion is warranted, allowing for *imperfect* multicollinearity. Belsley et al.^[15] further specify: “collinearity exists if there is a high multiple correlation when one of the variates is regressed on the others.” Heuristically, we can say that one variable is very nearly a linear combination of other variables. Obviously, this interferes with a classical assumption of regression analysis that the columns of the design matrix $\mathbf{X}$ are linearly independent.

Despite the fact that nonlinear models and limited dependent variable models are likely to be affected by

multicollinearity as well, multicollinearity as an issue is generally discussed in terms of least squares linear regressions and matrix algebra.^[18] With $\mathbf{y}$, an n -dimensional vector of observations on a dependent variate of interest; $\mathbf{X}$, an $n \times p$ matrix of measurements on p predictors x_i , $i = 1, \dots, p$ ($\mathbf{X}$ is the design matrix and contains all dependent variables included in the analysis); $\boldsymbol{\beta}$, a $p \times 1$ vector of parameters; and e , an $n \times 1$ vector of error terms, the linear regression equation can be written as: $y = \mathbf{X}\boldsymbol{\beta} + e$, $e \sim N(0, \sigma^2 I)$. Using standardized (dependent and independent) variables throughout this paper for ease of exposition, we can write the estimated parameter estimates $\hat{\boldsymbol{\beta}}$ in terms of correlations among covariates $\mathbf{R}_{xx}$, and correlations between covariates and dependent variable $\mathbf{R}_{xy}$, in the following way (e.g., Ref. [19]):

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1}(\mathbf{X}'\mathbf{y}) = \mathbf{R}_{xx}^{-1}\mathbf{R}_{xy} \quad (1)$$

$\mathbf{R}_{xx} = (r_{ij})_{1 \leq i, j \leq p}$, r_{ij} is the correlation between the variates x_i and x_j ; $\mathbf{R}_{xy} = (r_{ij})_{1 \leq i \leq p}$, r_{yi} is the correlation between y and x_i . Note that in the observation space, the orthogonal projection of $\mathbf{y}$ onto the (hyper)plane determined by the vectors that represent the covariates $x_1, \dots, x_p$ corresponds with $\hat{\mathbf{y}} = \mathbf{X}\hat{\boldsymbol{\beta}}$, that the coefficient of determination R^2 (proportion of the total variation in the dependent variable y that is explained or accounted for by the variation in the independent variable x_i) is the cosine between $\mathbf{y}$ and $\hat{\mathbf{y}}$, and that correlation r_{ij} is determined by the cosine between the vectors $\mathbf{x}_i$ and $\mathbf{x}_j$.

The variance of $\hat{\boldsymbol{\beta}}$ can be estimated via:^[19]

$$\hat{\sigma}^2 \left(\frac{1}{n} \mathbf{R}_{xx}^{-1} \right) = \left(\frac{n}{n-p} \right) \frac{|\mathbf{R}_{yx}|}{|\mathbf{R}_{xx}|} \left(\frac{1}{n} \mathbf{R}_{xx}^{-1} \right) \quad (2)$$

involving the $(p+1) \times (p+1)$ matrix $\mathbf{R}_{yx}$ of both correlations among covariates and correlations between covariates and dependent variable. Expression 1 clearly shows that when linear dependencies occur among covariates, $\mathbf{X}'\mathbf{X}$ will have a zero determinant, and the inverse will not exist; therefore parameter estimates will be undefined. Moreover, the relationship between covariates and response may modify the effects of multicollinearity in terms of precision of the regression parameter estimates. This is indicated by the occurrence of $\mathbf{R}_{yx}$ in Expression 2, and further discussed in Ref. [18]. These authors show that under certain conditions, multicollinearity may deflate parameter variance estimates, rather than inflate them (as usually mentioned by many authors, e.g., Ref. [20] or Ref. [21]).

TWO FACES OF THE SAME COIN

Dohoo et al.^[22] mention two sources of multicollinearity: sample-based and structural-based. The first source simply refers to all settings in which collected measurements on predictor variables appear to be correlated with a potential

for harmful multicollinearity (e.g., because they truly are, or because the same variables expressed in different units are used, etc.). The second source is because of ad hoc (after the data are collected) introduction of collinearity in the analysis (e.g., by including power terms in polynomial regression). Glantz and Slinker^[23] suggest to mean-center covariates before taking powers because this will usually be very effective in destroying strong relationships between the variates and their powers.

Suppose two variables x_1 and x_2 are measures of the same concept, but expressed in different units. In this extreme situation, the variables are maximally correlated ($r_{ij} = 1$) and essentially convey the same information. Many planes can be drawn through the line determined by the corresponding vectors x_1 (x_2), each of which yields the same residual vector $e (= y - \hat{y})$ and hence the same fit. However, many parameters exist to describe $\hat{y}$ as a linear combination of x_1 and x_2 . Suppose a third variable is added, say x_3 , geometrically orthogonal to x_1 but in the plane determined by y and x_1 . Then the overall model, including all three variables x_1 , x_2 , x_3 , fits the data perfectly. Neither x_1 nor x_2 will contribute significantly to the model after the other one is included. The overall fit is not affected by the multicollinearity. Removing both variables from the model would result in a much worse fit (coefficient of determination < 1).

Another extreme situation of multicollinearity arises in the presence of a suppressor variable. Such a variable is highly correlated with another independent variable but uncorrelated with the dependent variable.^[16] It may substantially increase the multiple correlation R^2 when combined with a variable that is only moderately correlated with the dependent variable. Suppressor variables may even lead to artificial interactions, as was shown by Sithisarankul et al.^[24]

HARMFUL MULTICOLLINEARITY

Despite the fact that multicollinearity is more a data problem than a statistical problem, it can cause severe problems in statistical modelling or model diagnostics. Multicollinearity “does not hurt as long as it does not bite.”^[15]

Slinker and Glantz^[25] specify that it “bites” when the analyses yield nonsensical results (in terms of clinical interpretation), parameter estimates of incorrect magnitude or incorrect sign (according to prior expectations), and huge standard errors leading to small observed test statistics, and accept too many null hypotheses. These symptoms are often combined as indicators for “harmful multicollinearity.”

When model selection is emphasized, multicollinearity is not much of a problem because predictions will still be accurate, and the overall R^2 can be seen as a quantification of how well the model predicts the y values. When the goal is to understand how the x variables influence y ,

then multicollinearity should be taken seriously. Because the confidence intervals may become extremely wide, excluding a subject (or adding a new one) may lead to dramatic changes in the estimated regression parameters or may even change their signs. In prognostic factor analysis, both issues are important. Here, the first step is to find a limited number of prognostic factor with a high impact on the response. The second step is to utilize these factors in categorizing patients to certain disease groups, as accurate as possible.

When the model is correctly specified, parameters are unbiased, even in the presence of multicollinearity. However, when model fit is based on a sample of the population at large, collinearity may result in inflated^[26] or deflated^[20] variance estimates. In reality, chances are high to select the wrong (i.e., incomplete) model. One believes that the model has the “correct” structure but parameter estimates may lead to erroneous interpretations about direction or magnitude of predictor variable effect on the response of interest. On a population basis, selecting the wrong model will lead to biased parameter estimates.^[21] On sample data, not only variable omission bias, but also problems with respect to proper variance estimation are to be expected, as Mela and Kopalle^[18] point out. Therefore it is important to properly detect and deal with multicollinearity.

The developed diagnostic tools in “Diagnostic Tool Kit” can be seen as ways to determine unacceptable multicollinearity and “harmful” multicollinearity, or a means to distinguish “acceptable” departures from orthogonality. In this setting, the aim is to detect evidence against the null hypothesis of orthogonality between independent variables. Note that orthogonal variables, being variables with zero covariance, are represented in the observation space as geometrically orthogonal vectors.

DIAGNOSTIC TOOL KIT

Unfortunately, there is no exclusive test that can tell you whether multicollinearity is or is not a problem. In the following, we briefly comment on some commonly used and less commonly used warning signals.

DETERMINANT

The absence of orthogonality immediately translates into $X'X > 0$. Transforming $\#X'X\#$ into an approximate chi-square statistic provides a statistical quantification for the interdependency between predictors.^[27] When x_i is orthogonal to the remaining set of predictors, the diagonal element xx_i of $(X'X)^{-1}$ satisfies $xx_i = [((X'X)^{-1})_{ii}]/(X'X) = 1$. The larger is the departure from orthogonality, the closer xx_i will become to infinity. The latter can be used as a means to locate a “troublesome” covariate. Alternatively, $[(n-p)/(p-1)](xx_i - 1)$, F -distributed with $n-p$ and $p-1$

degrees of freedom (under normality assumption of the dependent variables) can be taken to localize sources of multicollinearity.^[28]

CORRELATIONS

Klein^[29] indicates that a pairwise correlation r_{ij} bigger than the coefficient of determination R^2 is indicative of harmful multicollinearity. Extended to more than two predictors, Farrar and Glauber^[3] specify that a variable is harmfully multicollinear if its multiple correlation with other members of the independent set is greater than the dependent variables' multiple correlation with the entire predictor set.

However, no matter the strength of the relationship between dependent and independent variables, harmful multicollinearity is, in essence, an artifact of the independent data, via characteristics of the design matrix $\mathbf{X}$ (or $\mathbf{X}'\mathbf{X}$). Because large correlations between standardized variables will lead to large covariances and hence large departures from orthogonality, the correlation matrix is the first obvious object to look at in detail. In biological and physicochemical studies, intercorrelations of 0.90 or higher in absolute values are often considered as unacceptable.^[15,24,25,30] Some authors indicate pairwise absolute correlations of 0.70 or larger as signals for harmful multicollinearity.^[15]

Three important remarks are in place here. First, as mentioned before, "high" correlations are sufficient but not necessary for multicollinearity problems to arise. Second, the correlation matrix only allows for looking at pairwise relations between variates. Multicollinearities among three or more predictor variables can exist even though pairwise correlations are small. Third, relationships between dependent and independent variables can modify the "effects" of multicollinearity.

VARIANCE INFLATION FACTORS(VIFS)

The severity of multicollinearity may be suggested by the magnitude of the VIFs for the regression of each predictor on all remaining predictor variables. The VIF can be interpreted as the ratio of a parameter estimate's variance to what it would be in the absence of multicollinearity. It measures the inflation in the variance of the parameter estimate because of collinearity between the explanatory variable and other variables. In a three-variable regression setting, the VIF for β_1 is given by $VIF(\hat{\beta}_1) = 1/(1 - R_1^2)$, with R_1^2 , the unadjusted R^2 , regressing from x_1 onto x_2 and x_3 . A VIF larger than 10 is generally considered indicative of harmful multicollinearity (e.g., Ref. [31]), but this value is arbitrary, and relatively small VIFs may still point to instability. Some authors (e.g., Ref. [25]) accept a VIF > 4 (corresponding to an auxiliary regression R_1^2 of 0.75).

Note that the covariance matrix of the estimated regression parameters is $(\mathbf{X}'\mathbf{X})^{-1}\sigma^2$. When the variables are centered and scaled, $\sigma^2 = 1$ and the tolerance for the j th predictor is simply the j th diagonal element $xx_j = (1 - R_j^2)$ of $(\mathbf{X}'\mathbf{X})^{-1}$. Hence, when R_j^2 is close to one, the variable x_j does not add any further information to the remaining variables, the tolerance is 0, and the VIF for the j th parameter is infinitely large.

CONDITION NUMBERS

Alternatively, the structure of $\mathbf{X}'\mathbf{X}$, in particular the eigenvalues, can be examined. The literature suggests that eigenvalues smaller than 0.01 indicate a serious problem.^[25] The square root of the ratio of the largest to each individual eigenvalue is known as the condition index, and allows one to assess the relative magnitudes of the eigenvalues. The largest condition index (square root of the ratio of the largest to the smallest eigenvalue) is the condition number. A large such number is seen as evidence toward harmful multicollinearity. However, criteria for a condition number to signify serious multicollinearity are arbitrary, with values of 30–100 often quoted.^[31] But sometimes numbers as "small" as 2,015 or 1,025 are suggested as a cutoff.

BOOTSTRAP RESAMPLING

Bootstrap resampling is a less commonly used, but promising, diagnostic tool in the present context.^[32] Its usefulness is motivated on several levels. First, previously described diagnostic tools are derived from a linear regression model with normal error terms. However, regression is not the only technique that may be affected by harmful multicollinearity. Second, often, predictor variables are not continuous and are entered into the regression model in dichotomized form. This is particularly true in prognostic factor analyses. Third, the potential in variability (decrease in stability) for multicollinear regression coefficients impacts automated variable selection procedure. Backward selection may discard from the model what might be important variables. Forward selection may "fail" when neither of two correlated factors is identified as statistically significant, although both have an influence on the outcome.^[33] Therefore in the light of potential harmful multicollinearity, it is important to examine the stability of the chosen regression model. Stability may be defined by the replication stability for the choice of variables included in the model and the predictive ability of the model itself, as was suggested by Sauerbrei and Schumacher^[34] and further discussed in Schumacher et al.^[35]

This technique generates a number of samples (each the same size as the original data set) by randomly selecting

patients and replacing them before selecting the next patient (i.e., bootstrap resampling). The frequency of inclusion of the component variables in the regression models, fitted to each of these data sets (e.g., using automatic backward selection), can be considered to be indicative of the importance of the factors. Alternatively, these inclusion frequencies can be seen as estimates of the posterior probabilities that the regression coefficients are different from zero.^[34]

ACCOUNTING FOR MULTICOLLINEARITY OR AVOIDING THE PROBLEM?

A drastic way of avoiding the harmful effects of multicollinearity is to delete offending predictor variables from the model, based on some variables being redundant. However, despite overlap, variables may be explicitly designed to measure different aspects of a feature. So, it is not at all straightforward to argue for redundancy in such a situation.

Instead of deleting predictor variables, a weighted sum of the variables causing multicollinearity can be used. Substituting mathematically transformed variables for harmful ones or rescaling them may mitigate harmful multicollinearity.^[25] Nevertheless, such procedures may be hard to justify in the presence of nonnumerical data.

Alternatively, the number of explanatory variables is reduced by relying on multivariate data techniques and artificial orthogonalization of the covariate data (e.g., factor analysis or principal component analysis).^[31,36,37] By using principal components as new predictors, the initial intercorrelations between predictors are removed, yet a maximal amount of “information” in the data is retained. Although mathematically convenient, the question is how many components to retain or how to interpret the new constructs. In the majority of the cases, interpretation is not straightforward, not to say impossible. The same reasoning applies for factor analysis, in which the original variables are assumed to be a linear combination of factors plus an error term. Farrar and Glauber^[3] illustrate how backtransforming q factors (the “new” predictors) to p original variables (the “old” predictors), $q < p$, might actually compound multicollinearity.

Another route is to explicitly account for the presence of multicollinearity in the statistical technique chosen, such as Bayesian analysis or constrained regression.^[20] In a linear regression setting, multicollinearity can be accounted for by performing ridge regression, first proposed by Hoerl and Kennard.^[38] It is based on adding a (biasing) constant to the (nearly) singular matrix $\mathbf{X}'\mathbf{X}$. Although it leads to biased parameter estimates, a sensible choice of biasing constant may lead to a substantial reduction in the variance of the parameter estimates. Apart from being a remedial technique, it can also serve as a diagnostic tool for detecting predictors that elevate a multicollinearity problem. Sudden changes in the ridge estimates as the biasing

constant approaches zero can be seen as warning signals. Note that ridge estimators can also be used in logistic regression to improve the parameter estimates and to diminish error made by further predictions.^[39]

In “Alternative Ways to Go About Multicollinearity Issues,” we reconsider the examples introduced before, and offer some alternative ways to address multicollinearity.

ALTERNATIVE WAYS TO GO ABOUT MULTICOLLINEARITY ISSUES

Prognostic Factor Analysis Using QOL Measures

In a prognostic factor analysis^[32] incorporating clinical and QOL variables from the QLQ-C30 in a clinical trial of patients with advanced breast cancer, we observed instability in the model predicting response to chemotherapy because forward selection and backward elimination produced substantially different final multivariate models. This led us to suspect that harmful multicollinearity between QOL subscales was influencing model selection. Therefore we undertook a thorough examination of the QOL data used in the prognostic factor analysis to diagnose the presence and degree of multicollinearity, and to determine the stability of the predictive models obtained. In particular, replication stability of the final prognostic factor model was illustrated via a bootstrap resampling procedure based on works of Sauerbrei and Schumacher^[34] and Schumacher et al.^[35] and inclusion frequencies of predictor variables (based on 1000 simulated data sets) were reported (refer to Ref. [32]).

However, when we are interested in the “best set” of prognostic factors (which we usually are) rather than in the “best independent” prognostic factor, we need to account for the correlation structure of the potential prognostic factors under consideration. Therefore we calculated the model selection probabilities based on how many times a permissible model was selected in the bootstrap samples. The results are listed in Table 2. The relatively low frequency of each model (only the top 10 are shown) indicates that there is a serious inherent instability, without any model or group of models convincingly standing out. The top model seems to be indicative of dyspnea, with emotional functioning and fatigue being potentially important prognostic factors. However, caution is in place. The interpretation of the observed prognostic factors is not clearcut, even though the same three factors show up as good candidates when variable inclusion frequencies are used prior to bootstrap resampling (step 2; Table 2). Rather than believe in a single model, it is much more appropriate to use the model selection probabilities as weights, so as to obtain weighted averaged parameters,^[40] hereby incorporating effects of multicollinearity on model uncertainty.

Table 2 Results of the Bootstrap Model Selection Approach

Prognostic factors		10 models with the highest $h(M_j)$ % out of 233									
Step 1											
DY	79.20	*	*	*	*	*	*	*	*	—	—
PF	10.90	—	—	—	—	—	—	—	—	—	—
RF	7.20	—	—	—	—	—	—	—	—	—	—
EF	74.00	*	—	*	*	*	*	*	—	—	*
CF	10.00	—	—	—	—	—	—	—	—	—	—
SF	12.90	—	—	—	—	—	—	—	*	—	—
QL	14.80	—	—	—	*	—	—	—	—	—	—
FA	48.90	*	—	—	—	*	*	—	*	*	*
NV	31.40	—	*	*	—	*	—	—	—	—	—
PA	5.90	—	—	—	—	—	—	—	—	—	—
SL	8.30	—	—	—	—	—	—	—	—	—	—
AP	17.60	—	—	—	—	—	*	*	—	—	—
$h(M_j)$ %	$h(x_i) > 0.0\%$	13.4	5.4	5.0	3.1	2.9	2.8	2.5	2.4	2.2	2.2
Step 2											
$h(M_j)$ %	$h(x_i) > 0.1\%$	18.7	5.2	6.7	3.7	4.6	3.5	4.8	0.1	2.1	1.5
$h(M_j)$ %	$h(x_i) > 0.2\%$	39.1	8.3	11.7	0.0	8.6	0.0	0.0	0.0	3.7	3.2
$h(M_j)$ %	$h(x_i) > 0.3\%$	39.1	8.3	11.7	0.0	8.6	0.0	0.0	0.0	3.7	3.2
$h(M_j)$ %	$h(x_i) > 0.4\%$	59.7	0.0	0.0	0.0	0.0	0.0	0.0	0.0	5.4	5.9
$h(M_j)$ %	$h(x_i) > 0.5\%$	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0

The inclusion frequencies ($h(x_i)$) are based on the logistic regression models for response selected in 1000 bootstrap samples (automated forward selection), with treatment arm (ARM) included in the model and retaining the clinical variables disease-free interval (DFI) and dominant site of disease (DS). The corresponding model selection probabilities $h(M_j)$ resulting from different selection levels are also given. DY = dyspnea, PF = physical functioning, RF = role functioning, EF = emotional functioning, CF = cognitive functioning, SF = social functioning, QL = global quality of life, FA = fatigue, NV = nausea/vomiting, PA = pain, SL = insomnia, and AP = appetite loss.

GENETIC ASSOCIATION STUDIES AND EPISTASIS

In “Two Distinct Settings Where Multicollinearity Matters,” we indicated some of the potential drawbacks in terms of multicollinearity involved in using univariate logistic regression models for case-control genetic association studies. Alternatively, a multivariate approach can be adopted, in which genotype information is modeled conditional on disease status. It allows investigating the dependence of interactions on disease status and environmental factors. Missingness and error measurements in the covariates now become outcome problems; whereas the first can be integrated in the framework of missing data of Rubin,^[41] the second involves dealing with the residual errors. Although the problem of having many parameters to estimate remains, the problem of multicollinearity is alleviated. Van Steen et al.^[42] discuss merits of a particular multivariate model in this context, namely the multivariate Dale model. It extends the bivariate global odds ratio model described by Dale^[43] and McCullagh and Nelder.^[44] Joint probabilities are decomposed into main effects (described

by marginal probabilities) and interactions (described by odds ratios of second and higher orders).

Obviously, the aforementioned alternative ways to circumvent multicollinearity problems are of little use in the context of genomewide association studies (GWAs). The multi-dimensional character of GWAs, in particular when performing large-scale epistasis screening, and the gene-gene or protein-protein interaction networks that may impose complex dependencies between genetic markers, have paved the way for the revival of non-parametric pattern searching methods. Popular examples of such methods, which at the same time aim to reduce dimensionality with minimal information loss, include the non-parametric Multifactor Dimensionality Reduction method of Ritchie et al.^[45] and the semi-parametric Model-Based Multifactor Dimensionality Reduction approach of Calle et al.^[46]

DISCUSSION

There exists a vast literature on multicollinearity, which shows that the subject has occupied and still occupies

the minds of many scientists. This does not only relate to deriving an operable definition—it also relates to reconciling differing views on the severity of multicollinearity. In other words, is it really a problem? Is it harmful? Obviously, one can only talk about “harmful” multicollinearity when methods have been developed and used to detect it. This is not the end of the story though. Once detected, one of the key issues is to decide on ways to deal with the problem in further analyses—a matter of “avoiding” or “handling?”

Some people argue that the game is not worth the candle and that harmful multicollinearity, in terms of generating large standard errors of parameter estimates, is of the same order as having too small a sample size for modelling purposes.^[47] In a sense, this is true. However, it all depends on the purpose of your analysis. Whether it is in economics, clinical trials, or genetic epidemiology, the question is whether we are most interested in model selection or model testing. If the emphasis is on providing good predictions of the response variable, it does not matter whether or not selected factors are actually statistically significant—although, ideally, one hopes that the selected predictors (e.g., SNPs) in the model are true causal factors, or at least highly correlated to true causal variants.^[48] If the emphasis is on controlling the number of factors falsely included in the model, then multicollinearity issues do matter because, for example, large standard errors may lead to wide confidence intervals or small observed test statistics, and therefore reduce power to assess the significance of a factor.

In these cases, it is crucial to (i) identify, locate, and quantify harmful multicollinearity; and (ii) to overcome the problem or to use statistical tools that explicitly deal with multicollinearity issues.

The diagnostic tool kit at our disposal contains several signaling flags based on the matrix $X'X$ and its properties, or on measures of associations such as pairwise association r_{ij} or the coefficient of determination R^2 . In general, larger correlations, higher VIFs and condition indices, and lower determinants may all indicate an increased severity in harmful multicollinearity. The problem is how large should these quantities be for multicollinearity to be “unacceptable?” Cutoff values may differ from one field to the other and need to be “relaxed” because they are often derived under the assumption of multivariate normality. In addition, the majority of these diagnostics do not distinguish the direction of the correlations, nor do they include information about the strength of the relationship between explanatory variables and response. Mela and Kopalle^[18] show that the effects of multicollinearity are moderated by the relationship between the outcome variable and the predictor variables. Clearly, it can be very misleading to rely on a single diagnostic tool.

Because estimates of standard errors and parameters tend to be sensitive to changes in the data, an alternative route (complementing standard approaches) is to assess

model uncertainty or instability by adopting a bootstrap resampling approach. This technique generates a number of samples (each of the same size as the original data set) by randomly selecting observations and by replacing them before selecting the next observation (i.e., bootstrap resampling). Model averaging methodology naturally serves the purpose of explicitly incorporating model uncertainty in the analysis results.

CONCLUSION

One can always attempt to mitigate problems of multicollinearity. However, it is not always possible to overcome them. One such setting is a prognostic factor analysis, where most of the initial variables need to be entered into the model. Alternatively, strategies that explicitly account for harmful multicollinearity in the analysis are used. Here, the use of bootstrap models (to obtain greater insight into the stability of the models) and averaging procedures remain useful approaches, despite their computational intensive nature.

Abstract

This entry provides an overview of and comments on regularization regression procedures by first reviewing traditional penalized methods, and then Lasso and its extensions, and also discussing some penalty function designs that lead to bias reduction methods.

Keywords: Bias-reduction technique; Multi-dimensional data; Penalized regression; Two-step model building; Variable selection.

INTRODUCTION

Developments in bio-imaging technology have made it possible to widely use genome-wide experiments to do whole-genome analyses of Single Nucleotide Polymorphism (SNP) patterns, microarray-based gene expression analyses, and modern-mass-spectrometry-based protein expression analyses to study many health related issues. These new technologies allow observing thousands of SNP, mRNA expression, or protein expression measurements in a single assay, thus providing massive amounts of biological data on study samples. There has been a substantial impact on disease subtyping as a result of the discovery of biomarkers that can be used in a wide range of applications, for example, quantifying individual risk and/or its modification by non-host (environmental) factors based on host genetic (SNP) patterns, detecting disease in an earlier stage than currently possible, enabling molecular classifications of diseases for accurate targeting by therapies, and predicting patient prognosis and/or determining the best (tailored) therapy based on the expression profiles of the patient and his or her disease. While these new technologies offer tremendous promise, a number of critical issues need to be resolved in order to achieve and maximize their utilities for use in therapeutic and preventive medicine.

Statistics methods play a vital part of these new biological analyses. Statistics methods are required, for example, in the normalization of expression from multiple arrays, in selecting significant differentially expressed features, in tumor classifications, and in expression pathways and networks analysis. The statistical challenges involved in defining the characteristics of expression-based studies include: (i) there is a much larger number of features

contributing expression measures, which far exceeds the number of observations available, and (ii) by virtue of pathway (or network) relationships, the expression measures tend to be highly correlated. These challenges have spawned several new methodological approaches to adopt penalization techniques for model/feature selection, for example, Lasso^[1] and adaptive Lasso^[2], and SCAD^[3] and non-negative garrote.^[4] Commonly used algorithms include LARS,^[5] LQA,^[3] and MM.^[6] In this chapter, we provide a overview of and comments on these regularization regression procedures.

PENALIZED APPROACHES

The general form of a penalization technique can be described as *loss + penalty*. Under a selected *penalty* function, change of *loss* leads to various types of regression models. The least-square loss leads to a regularized linear model; a negative log-likelihood loss leads to a regularized likelihood model; and a hinge-loss function leads to a support-vector machine model. In this section we address a key aspect of using a penalization technique: choosing a penalty function. We first review traditional penalized methods, and then *Lasso* and its extensions. Finally, we discuss some penalty function designs that lead to bias reduction methods.

Traditional Penalized Methods

L_0 Penalty (or Entropy)

The entropy penalty function can be described as $p_\lambda(|\theta|) = \frac{1}{2} \lambda^2 I(|\theta| \neq 0)$. Here and after, λ (or λ_1 and λ_2)

is used to present tuning parameter(s). If we denote $|M|$ as the number of variables selected in a model and focus on finding a model with $|M| \leq t$, then we can use $\frac{1}{2} \lambda^2 \sum_{j=1}^p I(|\beta_j| \neq 0) = \frac{1}{2} \lambda^2 |M|$ in the following penalized least-square problem:

$$\min \frac{1}{2n} \sum_{i=1}^n \left(y_i - \sum_{j=1}^p x_{ij} \beta_j \right)^2 + \frac{1}{2} \lambda^2 |M|, \quad (1)$$

where $\{(y_i, x_{i1}, \dots, x_{ip}), i = 1, \dots, n\}$ is a sample set of n observations, and $\beta_j, j = 1, \dots, p$ are coefficients to be estimated.

This optimization problem leads to the traditional ordinary least-square model selection methods including *stepwise* and *all-subsets regression* procedures. These procedures pick predictors and then use least squares or maximum likelihood to estimate the coefficients. In other words, they focus on variable selection and do nothing specific to estimate parameters. Although these methods produce a sparse model, they have several drawbacks: (i) theoretical properties can be hard to understand, (ii) estimates are extremely variable because of their inherent discreteness, as addressed by Breiman,^[7] and (iii) computational costs are very high as p gets large.

L_2 Penalty (or Ridge)

The L_2 penalty function $P(|\theta|) = \theta^2$ leads to the popular ridge regression.^[8] It achieves improved prediction accuracy via shrinkage. In a linear regression situation, ridge regression achieves coefficients shrinkage by a constraint $\sum_{j=1}^p \beta_j^2 \leq t$. An equivalent formulation is afforded by L_2 penalized regression:

$$\min \frac{1}{2n} \sum_{i=1}^n \left(y_i - \sum_{j=1}^p x_{ij} \beta_j \right)^2 + \frac{1}{2} \lambda \sum_{j=1}^p \beta_j^2, \quad (2)$$

In contrast to the entropy, ridge regression is not concerned with variable selection (it uses all candidate predictors). Rather, it deals with how coefficients are estimated. Although ridge penalization does not produce unbiased estimators and a parsimonious model, it achieves better prediction performance than a pure least-square estimation through a bias-variance tradeoff, especially when the predictors in the model are highly correlated. Numerous studies have shown that ridge penalization is an effective tool for dealing with co-linearity among predictors. Ridge regression can be obtained efficiently via standard quadratic programming when $p \leq n$ or dual algorithms when $p > n$.

Lasso and Its Extensions

Lasso. In a linear regression situation, the L_1 penalty function $p_\lambda(|\theta|) = \lambda|\theta|$ leads to Lasso^[1] (the least absolute

shrinkage and selection operator). Lasso is a shrinkage method similar to ridge, with subtle but important differences. The Lasso estimator is a solution to the minimization of the residual sum of squares, subject to a constraint on the sum of absolute values of the regression coefficients $\sum_{j=1}^p |\beta_j| \leq t$. It is equivalent to the following regularized least-square problem with an L_1 penalty

$$\min \frac{1}{2n} \sum_{i=1}^n \left(y_i - \sum_{j=1}^p x_{ij} \beta_j \right)^2 + \lambda \sum_{j=1}^p |\beta_j|. \quad (3)$$

The Lasso method combines the desirable features of ridge regression and subset selection procedures. Firstly, similar to subset selection, the L_1 penalty results in variable selection. Because of the nature of the constraint, making λ large enough or equivalently t sufficiently small will cause some of the coefficients to be (estimated as) exactly zero, as variables with coefficients of zero are effectively eliminated from the model. Another important feature of the L_1 is that its shrinkage property is similar to ridge. The big difference between ridge and lasso is that ridge shrinks the coefficients toward zero proportionally to the value of the coefficients and lasso exerts the same force on all nonzero coefficients. Hence for significant variables, the shrinkage towards zero of an L_1 penalty is less than that of an L_2 penalty. This is important for providing accurate predictions of future values in high-dimensional situations.

Efron et al.^[5] developed Lars (least angle regressions) as an efficient algorithm for computing the whole Lasso solution path as λ is varied. The Lars method can be viewed as a stagewise method, which accelerate the computations using mathematical formulas. Their algorithm exploits the fact that the coefficient profiles are piecewise linear, which leads to computational costs as low as the full least-squares fit on the data. Lars has some remarkable properties. The first one is speed: the entire sequence of the Lars steps with $p < n$ variables requires $O(p^3 + np^2)$ computations—the cost of a least-square fit on p variables. Second, the basic Lars algorithm, which is based on the geometry of angle bisection, can be used efficiently to fit Lasso and stagewise models, with certain modifications in higher dimensions.

Elastic net. Zou and Hastie have proposed the elastic-net approach:^[9]

$$\min \frac{1}{2n} \sum_{i=1}^n \left(y_i - \sum_{j=1}^p x_{ij} \beta_j \right)^2 + \lambda_1 \sum_{j=1}^p |\beta_j| + \frac{\lambda_2}{2} \sum_{j=1}^p \beta_j^2 \quad (4)$$

The elastic-net penalty can be viewed as a compromise between ridge and Lasso. The shrinkage behavior of the elastic-net penalty on small coefficients is much like that of Lasso, with almost the same shrinkage amount toward zero; the behavior on large coefficients is as heavy as ridge, proportional to the absolute value of the coefficients.

An intuitive aspect of this method is that the L_1 penalty eliminates redundant variables and the L_2 penalty deals with possible high correlation among predictors.

The elastic-net approach has the following properties: (i) similar to Lasso, it produces a sparse model by variable selection; (ii) similar to ridge, it shrinks toward zero for non-zero coefficients and shrinks together the coefficients of correlated predictors; and (iii) for a fixed λ_2 , the elastic net solution path as λ_1 varied can be computed efficiently using the Lars algorithm. With a suitable L_2 penalization, elastic net can provide a more stable predictive performance than Lasso when predictors are highly correlated. This is the main difference between Lasso and elastic net.

Extensions or Alternative to Lasso

The Lasso approach laid down the groundwork for high-dimensional analysis and thus became a popular regression method with attractive features. This idea has been applied broadly to generalized linear models and Cox's proportional hazard models.^[10] Recently, a variety of research activities have been devoted to related penalization methods. These include (i) the fused Lasso^[11] for a sequence of predictors where there is a natural ordering of the predictors and the coefficients for nearby predictors are normally similar; (ii) the group Lasso,^[12] which handle groups of predictors with a natural grouping, for example, sets of bases for smoothing splines and sets of dummy variables representing levels of factors; (iii) the L_1 realization path for the SVM^[13] (support-vector machine); (iv) the Dantzig selector,^[14] a modified version of the Lasso; and (v) the graphical Lasso^[15] for sparse covariance estimation and undirected graphs.

Bias Reduction Methods

SCAD and Its Oracle Property

Fan and Li^[3] observe that a good penalty function results in an estimator with three properties: *unbiasedness*, so that the resulting estimator is nearly unbiased when the unknown coefficient of the regression is large; *sparsity*, so that the resulting estimator has an automatic thresholding rule that sets some estimated coefficients to zero to reduce the complexity of the model if the estimated values are small; *continuity*, so that the resulting estimator is a continuous function of data to avoid instability in model prediction.

Fan and Li^[3] discuss various penalty functions in terms of the above three properties and establish the conditions for a penalty function that satisfies them. Their work has led to the development of a new penalty function, SCAD, a non-concave penalty function that has been widely used in penalization techniques in different statistical contexts. Its related penalization technique is considered to produce estimators that are less biased than estimators produced by the Lasso approach.

The proposed SCAD is a continuous differentiable function defined by

$$P'_\lambda(\theta) = \lambda \left\{ I(\theta \leq \lambda) + \frac{(a\lambda - \theta)}{(a-1)\lambda} I(\theta > \lambda) \right\},$$

for $a > 2$ and $\theta > 0$ (where A_+ is defined as the positive part of A). Different from various L_q penalties, SCAD is a non-concave penalty function. It leads to the following penalized least square

$$\min \frac{1}{2n} \sum_{i=1}^n \left(y_i - \sum_{j=1}^p x_{ij} \beta_j \right)^2 + \sum_{j=1}^p P_\lambda(|\beta_j|). \quad (5)$$

Fan and Li^[3] note that SCAD results in an estimator with three properties: *unbiasedness*, *sparsity*, and *continuity*. The most attractive aspect of SCAD is that it does not penalize coefficients with large values. This property makes the SCAD estimator asymptotically equivalent to an oracle estimator, which is obtained by deleting all irrelevant predictor variables. This result implies that SCAD can achieve consistent model selection and optimal prediction simultaneously as the sample size increases. Their work has laid down the groundwork for variable selection problems in the finite parameter setting. Further studies related to SCAD penalization, including theoretical analysis and extensions to other loss situations, can be found in the literature,^[6,16,17] among others.

The solution to (5) can be calculated using LQA^[3] (local quadratic approximation), which turns (5) into an iterative high-dimensional quadratic program problem.

Combined Penalty (CP)

Wang et al.^[18] proposed a new combined penalization technique. In a linear regression situation, the regularized least-square can be expressed as follows:

$$\min \frac{1}{2n} \sum_{i=1}^n \left(y_i - \sum_{j=1}^p x_{ij} \beta_j \right)^2 + \sum_{j=1}^p J_{\lambda_1, \lambda_2}(|\beta_j|). \quad (6)$$

The combined penalty function $J_{\lambda_1, \lambda_2}(|\beta_j|) = \sum_{j=1}^p \left(P_{\lambda_1}(|\beta_j|) + \frac{\lambda_2}{2} \beta_j^2 \right)$ is a compromise between ridge and SCAD.

The penalty in Eq. (6) has two separate functions. As described,^[18] the SCAD is adopted mainly for eliminating redundant features, and the ridge can give suitable shrinkage to non-zero coefficients and reduce the influence of highly correlated predictors. This flexible design allows us to adjust the penalty and make it suitable for various data settings, for example, when $p \gg n$ and the strength of the data is too weak to provide distinct and true features from a highly correlated feature cluster. In this case, we should use relatively heavier

L_2 penalization or heavier shrinkage to non-zero coefficients. At the other extreme, if $n \gg p$ and the data is strong enough to detect all the significant features, reducing the unnecessary estimation bias of the coefficients using a very small value of λ_2 may help to reduce predictive error.^[18]

Here, we emphasize that incorporating the ridge penalty to deal with colinearity among predictors is very important in high-dimensional data analysis. As pointed out,^[17] even when the predictors are independent, the maximum sample correlation can become high as the dimension becomes large. Hence, one crucial aspect of choosing a penalty function is deciding how to deal with high-colinearity among predictors. In other words, shrinkage of large coefficients is necessary in high dimensional settings.

Wang et al.^[18] proved that, similar to SCAD, the combined penalization technique results in an estimator with three properties: *sparsity*, *continuity*, and asymptotically enjoying the so-called *oracle* property under some regular conditions. As $\lambda_2 > 0$, the estimator of (6) is no longer unbiased, but it is *asymptotically unbiased* as $\lambda_2 \rightarrow 0$.

The solution to (6) can be calculated using LQA to turn (6) into an iterative quadratic program problem and using a dual algorithm to overcome the computational burden related to the high-dimensional quadratic program.

Two-Step Strategy

Lasso is an attractive regularization method for high-dimensional data analysis that combines variable selection with an efficient computational procedure. However, the rate of convergence of the Lasso is slow for some sparse high-dimensional data, as the number of predictor variables grows with the number of observations. The reason can be traced back to the biased nature of the Lasso. Fan and Li^[3] first pointed out that asymptotically the Lasso has a non-ignorable bias for estimating non-zero coefficients. To overcome this difficulty, two-step model building procedures are proposed to reduce the bias in estimation.

Relaxed Lasso

One example is the relaxed Lasso proposed by Meinshausen.^[19] For $\lambda \in [0, \infty)$ and $\phi \in (0, 1]$, in the first step, select a subset of variables $M_\lambda = \{1 \leq j \leq p \mid \hat{\beta}_j^\lambda\}$ using Lasso

$$\hat{\beta}^\lambda = \arg \min_{\beta} \frac{1}{2n} \sum_{i=1}^n \left(y_i - \sum_{j=1}^p x_{ij} \beta_j \right)^2 + \lambda \sum_{j=1}^p |\beta_j|. \quad (7)$$

Then in the second step, the relaxed Lasso estimator is defined as the solution of the following penalized least-square problem:

$$\min \frac{1}{2n} \sum_{i=1}^n \left(y_i - \sum_{j=1}^p x_{ij} \beta_j I_{M_\lambda}(j) \right)^2 + \phi \lambda \sum_{j=1}^p |\beta_j|, \quad (8)$$

where $I_{M_\lambda}(\cdot)$ is an indicator function on the subset of variables M_λ in $\{1, \dots, p\}$. The first step can be considered as a feature-selection step, while in the second coefficient-estimation step the parameter $\phi \leq 1$ relaxes the penalty and reduces the bias of the coefficient estimation.

When we have enough information from the data, we can expect that with a suitably chosen λ , the subset M_λ can cover all or most of the significant features. Then relaxing the penalty can give a better parameter estimation. Meinshausen^[19] proved that, as n tends to ∞ , the convergence rate of $\text{IE} \sum_{i=1}^n \left(y_i - \sum_{j=1}^p x_{ij} \hat{\beta}_j \right)^2 - \sigma^2$ is almost unaffected by the number of predictors if the tuning parameters λ and ϕ are chosen appropriately.

Adaptive Lasso and Elastic Net

Other examples of the two-step strategy include adaptive Lasso and adaptive elastic net. Zou^[2] proposed the adaptive Lasso estimator

$$\min \frac{1}{2n} \sum_{i=1}^n \left(y_i - \sum_{j=1}^p x_{ij} \beta_j \right)^2 + \lambda \sum_{j=1}^p \hat{w}_j |\beta_j| \quad (9)$$

where $\hat{w}_j, j = 1, \dots, p$ are the adaptive data-driven weights and can be computed by $\hat{w}_j = (|\beta_j^{\text{ini}}|)^{-\gamma}$, with γ a positive constant and β_j^{ini} an initial root-n consistent estimate of the coefficient β_j . Setting the adaptive data-driven weights lets the penalty enforce different levels of penalization on coefficients based on their performance in the initial estimate. The essential idea behind this approach is similar to that of SCAD: larger coefficients receive fewer penalties. Zou^[2] showed that under some regularity conditions the adapted Lasso performs asymptotically as well as the oracle.

The adaptive elastic-net^[20] combines elastic-net with the technique of adaptive data-driven weight used in adaptive Lasso. Similar to adaptive Lasso, the adaptive elastic net can be viewed as a two-step model building procedure. In the first step we use elastic net

$$\min \frac{1}{2n} \sum_{i=1}^n \left(y_i - \sum_{j=1}^p x_{ij} \beta_j \right)^2 + \sum_{j=1}^p (\lambda_1 |\beta_j| + \lambda_2 \beta_j^2). \quad (10)$$

to get initial estimates of the coefficients $\beta_j^{\text{ini}}, j = 1, \dots, n$. In the second step an adaptive elastic net can be estimated from the following adaptive weighted optimal problem:

$$\min \frac{1}{2n} \sum_{i=1}^n \left(y_i - \sum_{j=1}^p x_{ij} \beta_j \right)^2 + \sum_{j=1}^p (\lambda_1^* \hat{w}_j |\beta_j| + \lambda_2 \beta_j^2) \quad (11)$$

where $\hat{w}_j, j = 1, \dots, p$ are the adaptive data-driven weights and can be computed by $\hat{w}_j = (|\beta_j^{\text{ini}}|)^{-\gamma}$, and λ_1^* is a new L_1 tuning parameter value different from that of λ_1 in (10).

Similar to adaptive Lasso, the adaptive elastic-net also performs asymptotically as well as the oracle.

TUNING AND FEATURE SELECTION ISSUES

Tuning issues are crucially important in feature/model selection in the context of high-dimensional regression. The distinguishing characteristics of genome-wide studies ($p \gg n$ and highly correlated expression measures) make feature selection and tuning very difficult. Here, we discuss issues related to the two principal means of tuning: one is criteria-based and the other is prediction error-based. Similar to the previous section, our discussion focuses on the setting with least-squares loss.

A variety of criteria developed for classical model selection studies (in the $n \geq p$ setting) have been used for model selection problems in high-dimensional settings, including AIC^[21] (Akaike Information Criterion), C_p ^[22], BIC^[23] (Bayesian Information Criterion), and ϕ -criterion.^[24] Common to all these approaches is penalization of training error estimates as well as the need to estimate the residual variance σ^2 of the full model. However, estimating σ^2 is problematic, because a full model will yield $\hat{\sigma}^2 = 0$ as $p \gg n$.

The merit of K-fold CV (Cross-Validation), which bases model selection on prediction error determination, has been convincingly advanced (see Breiman^[25]). But CV can also be problematic, as $p \gg n$, especially when n is small. The difficulties mainly come from the large variability of CV estimates of the prediction error.

The distinguishing characteristics of genome-wide studies ($p \gg n$ and highly correlated expression measures) contribute to the instability of feature and model selection, that is, the existence of the so-called “Rashomon effects” (see Berman^[25])—many competing distinct models with comparably good performance.

In a regression problem with a limited dimension and a sufficiently large number of observations, a small disturbance of data will not alter the final selected model very much. In a complex high-dimensional problem, however, a small perturbation of data could lead to a selection of a totally different feature subset, because the sample size is often limited relative to the dimension and noise levels of data. This is one of the potential reasons why different studies with an identical biomarker-discovery aim could lead to inconsistent results in gene/protein expression analysis.

All these difficulties in both tuning and model selection arise from the distinguishing characteristics of genome-wide studies ($p \gg n$ and highly correlated expression measures). The data used for regression usually does not have enough information strength. This implies that the difficulties are not from lack of statistical method developments, and hence cannot be overcome easily by developing even more powerful statistical techniques.

CONCLUSIONS

The purpose of this entry is twofold: the first is to review and comment on the current state of penalization regression techniques and second is to explain the “sensitivity”—a common phenomenon related to expression-based biological studies and other high-dimensional data analyses.

All these penalization methods are designed for high-dimensional analysis. The Lasso and elastic-net have considerable promise, offering speed, relatively stable predictions and interpretability. Alternate penalization techniques such as SCAD, CP, adaptive Lasso, and adaptive elastic-net have advantages for certain kinds of data. Adopting “bias-reduction” strategy allows them asymptotically enjoying the so-called *oracle* property under some regular conditions. While whether these “bias-reduction” techniques can get higher predictability than Lasso/Enet depends on “information strength” included in data. Further work is still needed to investigate performance of these methods.

The difficulties in tuning and “sensitivity” in model selection arise from the distinguishing characteristics of genome-wide studies ($p \gg n$ and highly correlated expression measures). Since these issues arise due to the fact that the data used for regression does not have enough information strength, it is impossible to completely overcome these difficulties by developing more powerful statistical techniques. We believe that an essential remedy is to add new information to the data, either providing a larger data set by combining information from several genome-wide experiments or providing new structure/cluster information on the expression data.

Multinational Clinical Trials

Thomas R. Weihrauch

Bayer AG, Wuppertal, Germany

Abstract

Multinational clinical trials are, in most cases, set up in order to complete the trial more rapidly when one country cannot provide an adequate number of patients to meet the sample size requirements. This entry discusses the procedural details, advantages, and obstacles of a multinational clinical trial.

INTRODUCTION

Multinational clinical trials of investigational drugs or of approved drugs for new indications have become increasingly popular over these past several years. In most cases, they are set up in order to complete the trial more rapidly, particularly when the condition under study has a low incidence and any one country cannot provide an adequate number of patients to meet the sample size requirements and the study time table. Experience at Bayer indicates that the number of such trials has increased as has the number of participating centers and the overall costs per trial. Moreover, the preparation, evaluation, and documentation for such trials is more extensive than it is for multicenter trials performed in one country. The obstacles to multinational trials are manifold and they arise from differences in standard and style of medical practice, differences in drug regulations and differences of medical culture, not to mention the difficulties inherent in organizing the trial itself. There are, however, many advantages to this type of investigation because it permits a more rapid enrollment of patients by a wide range of treating physicians in a variety of international medical institutions. Such trials are best performed, however, in countries and centers that have similar medical standards and practice. From the drafting of the protocol to the publication of the final results, the successful performance of a multinational trial requires an optimal level of teamwork, a strong study coordination, and most importantly, a committed and highly motivated expert panel of international investigators.

OVERVIEW

Clinical trials provide the basis for assessing the efficacy and safety of investigational drugs or of approved drugs for new indications. In order to gain approval by International Regulatory Authorities and acceptance by the medical community, large randomized, controlled, double blind trials

are often performed in Phase III of clinical development. In many instances, investigational centers from several countries participate in such trials and become part of a multinational effort. There are many obvious advantages of such an approach, but there are also some drawbacks or obstacles. Despite these, however, multinational clinical trials have become increasingly common in clinical research. Reviews on the more general aspects of this approach have been published by Mondan,^[1] and Spilker,^[2] and our group.^[3,4] This paper will address some of the more pragmatic issues applicable to this subject based on the experience that the Pharmaceutical Division of Bayer has gained over these past several years. The subject is of no small interest because it should be recognized that major advances in the therapy of such devastating diseases as acquired immunodeficiency syndrome (AIDS) and cancer will likely only come about through the performance of high-quality, multicenter trials, which in many instances, will be multinational.

ADVANTAGES

The availability of suitable patients for a specific study may be compromised because of the low incidence of disease under investigation or because of the stringent inclusion or exclusion criteria of the study protocol. For example, multinational clinical trials have been used to investigate new drugs for the treatment of angina pectoris because of the detailed and strict guidelines that must be followed to prove efficacy in this condition.

The enrollment of patients into a study may also be difficult because the protocol may require special testing or equipment, which may not be standard in all hospitals. For a medication that was intended for use in emergency circumstances, one of our studies could only be performed in centers that had ambulances with special equipment for drug delivery and specially trained personnel. Because of these prerequisites, the study had to include centers from several countries in Europe.

The enrollment of a large number of patients from a multitude of centers from different countries permits the demonstration of a drug's efficacy and safety under varying conditions such as lifestyle, diet, and concomitant therapy. Moreover, larger trials provide a greater opportunity for physician investigators to participate in innovative clinical research and to gain firsthand experience with new agents. Their patients profit likewise, first from the opportunity of receiving a new potentially important therapeutic modality, and second, by the special attention and care that must be given to all patients enrolled in study protocol.

OBSTACLES

Anyone who has experienced the challenge of organizing a multinational clinical trial is aware of the many obstacles that must be overcome to successfully complete the trial. Obstacles common to multicenter trials within one country are usually compounded or amplified when the attempt is made to carry out a multinational effort. Some of these factors are addressed below.

Regulatory

Although much progress has been made regarding the harmonization of the regulatory framework for clinical development of new drugs, there are still discrepancies from one country to another. For example, if a transatlantic trial is planned with a treatment duration of 3 months, the clinical investigators in Europe must await completion and clearance of a 6-month toxicology study whereas their U.S. colleagues may commence on the basis of only 3 months' toxicology data.

A further obstacle may arise from the difficult legal requirements of informed consent. For example, in Germany, patients with altered mental function or those in coma with stroke or head injury may not be able to give consent and therefore are not eligible for study.

For new therapeutic principles in life-threatening conditions, it is not uncommon that ethical review committees have varying opinions. This may be a result of different standard of therapy or may be related to different views on the ethics of treatment procedures. Although, in some countries such as Germany, ethics committees do not formally approve protocols but rather give advice, it is highly recommended that agreement on the protocol be obtained from all committees that are involved in protocol evaluation.

Medical Culture and Practice

Differences in cultural background among the participating countries may provide stumbling blocks to the smooth progression of the trial. For example, in Germany the condition impaired brain function of old age is not recognized

in Anglo-Saxon countries and requires different inclusion criteria and treatment than, for example, Alzheimer's disease. The diversity of language alone may impact on the classification of the condition to be treated. A number of misunderstandings may arise when Anglo-Saxon abbreviations are used which are abstruse to investigators who are not thoroughly familiar with the English language. These have the potential to cause confusion and often miscommunication.

In a major multinational clinical trial of stroke sponsored by Bayer, centers from Great Britain had to be excluded because of the different therapeutic strategies practiced there as compared with continental Europe. In Great Britain conservative management was more prevalent, whereas in Europe a more aggressive approach to therapy was practiced.

It is well accepted that the exposure to risk factors for coronary artery disease because of diet differs between people of nordic and mediterranean countries in Europe. In studies of metabolic diseases, such as diabetes or hypolipoproteinemia, diet may have to be standardized with the disadvantage that the results then may not be applicable to the daily routine of patients in individual countries.

The diversity in medical culture and practice should not be underestimated in the establishment of a multinational trial because this could have serious consequences on the outcome. This must be considered at an early stage and may lead to stratification of patients, the exclusion of certain patients, or even the exclusion of certain centers or countries from participation.

Clinical Parameters

Within a multinational clinical trial, key elements of the study protocol must be standardized. This sometimes poses problems in the area of clinical parameters because they may vary greatly from one region to another in established indications, as in the case of angina pectoris (time to onset of angina vs. onset of change in the electrocardiogram). Psychometric tests are difficult to standardize and, in order to address this difficulty, we have had to perform studies using two or three parallel scores for important efficacy variables.

Reference Drugs

Reference drugs are included in Phase IIB and Phase III clinical trials as active controls and are required in a number of countries to provide price comparisons for health authorities. For a multinational clinical trial, the inclusion of reference drugs is often a problem because of factors such as labeling, formulations, appearances, names, and even countries of origin. The same holds true for comedication or standard therapy, if the investigational drug is add-on.

Adverse Events

Reporting of adverse events (AEs) may pose a problem because of the different approaches used in different countries, particularly with respect to the formulation, format, and the time period allowed for reporting. All AEs are of interest but the prompt reporting of serious or unexpected events must be assured; they must also be evaluated immediately as they may be the first indication that a study must be stopped because of an unfavorable risk/benefit ratio. The standard reporting guidelines and the standard operating procedures carefully developed by most sponsors of major multinational trials are now streamlining this process. Moreover, the international introduction and implementation of Good Clinical Practices (GCPs) is doing much to improve the timely reporting of more precise information on AEs.

Health Care Systems

Health care systems differ widely among countries and may influence the standard therapy used for specific diseases (reimbursement policy). In addition to possibly affecting the overall outcome of a specific illness, these differences may render multinational clinical trials on the cost effectiveness of new therapy very difficult or even impossible.

POINTS TO CONSIDER

Listed below are some of the important points to consider when preparing for and carrying out a multinational clinical trial.

Coordination

Critical to the success of the trial is the establishment of an effective coordination function which plays a pivotal role in all aspects of the project. At Bayer, this function resides with the coordinator of the multinational study (CMS). The CMS is appointed by medical research management and reports functionally to the International Clinical Project Manager. The CMS is the intermediary between the clinical project leaders (CPLs) of the different medical departments involved in the trial and the central services departments of Bayer.

Depending upon the size of the trial and other factors, it may be desirable to establish committees or individuals responsible for selected functions. The following are a list of some of the functions that may require specific supervision:

- Drafting and finalizing the trial protocol.
- Regulatory activities.
- Tracking study supplies.
- Clinical Quality Assurance (CQA).

- Data management/statistical analysis.
- Safety committee (an individual or individuals not associated with the trial, but usually within Bayer, who will assess AEs and their reportability to regulatory authorities as well as their impact on the course of the study).
- An independent Extramural Review Committee (experts in the study area responsible for reviewing each Case Report Form (CRF) to determine validity and other aspects of patient management and to provide expert advice on efficacy and safety issues that may arise during the study).
- Data Analysis and Review Team/Manuscript Review Committee (usually composed of key investigators who will provide input on data analysis and on the generation of the study manuscript).

Whether or not committees are formed or whether these functions are taken over by individuals, the responsibilities must be clearly defined very early in trial development so that confusion, inefficiency, and delays may be avoided.

The CMS for the trial must work in concert with all of these functions and with the CPLs in the participating countries who maintain full local responsibility. An effective and continued communication between the CMS and CPL is essential not only in the planning phase, when the national characteristics of each country may be discussed and considered in protocol development, but also during patient recruitment so that any problems which may arise may be rapidly resolved.

The overall manpower needs for the trial will depend principally on the complexity of the protocol and CRF, and on the number of centers and patients to be included as well as the expected rate of patient enrollment. To provide optimal human resources, the needs of both the coordinating country and all participating countries must be carefully determined.

Outline of the Trial

To establish the feasibility of a multinational clinical trial, a concrete study outline should be prepared early and provided to CPLs in countries of interest. This document permits each CPL to evaluate the potential for participation and to determine resource requirements, which can then be discussed with local Medical Direction. The trial outline must include the condition and population of patients to be studied (inclusion and exclusion criteria, the nature of the comparative drugs, their dosage, and conditions of use).

Time lost in clinical trials is often caused by overoptimistic estimation of the number of patients available for study. This is usually a function of the inclusion and exclusion criteria defined in the protocol and can make the fraction of suitable patients sometimes surprisingly small. Very slow patient enrollment can become demoralizing not only

to the sponsor but also to the investigator team. Realistic estimates of patient availability must be made and, in some cases, it may even be desirable to do a pilot study to test a protocol before embarking on any major project.

Protocol Development

Considering the potential problems that may arise as a result of differences in medical culture and practice, it is critical that all participating investigators reach precise agreement on the study protocol. The objectives of the study must be clearly understood and investigators must reconcile these with the given conditions within their own institutions. The progression from the rough outline of a study to the final version of the protocol for a multinational clinical trial may take months of careful deliberation among experts of various disciplines. This process should be effectively led by a company staff member usually in concert with a principle investigator.

The Case Report Form

In developing the CRF for a multinational clinical trial, there are several issues that need special attention. For example, when one common language is used, it is imperative that all terms be clearly understood along the entire chain of personnel involved in the trial. It may appear self-evident but the understanding must first start with the team that prepares or designs the form and proceed to the local CPLs, investigators, and very importantly, to the investigational team member who will complete the CRF on site. Of course, those individuals monitoring the trial including any Contract Research Organization (CRO) personnel must also be thoroughly knowledgeable about the form. Finally, the data analysis or biometrics team must be resident experts. One of the more critical aspects of the CRF is the coding of free text entries such as AEs or investigator comments. It is important that these entries be clear and consistent with a commonly used glossary and that any ambiguities of language be clarified before the data are computer key punched.

Prestudy investigator meetings, during which the CRF is carefully reviewed, will do much to foster common understanding. However, a comprehensive written CRF Guide will be an extremely useful document to have available at study start up. The guide should be updated periodically by the CMS during the study as new and unanticipated issues arise which need clarification. Such a guide will do much to not only ensure consistency and quality of data, but will also serve to facilitate the eventual data processing.

If CRFs are translated into different languages, it is imperative that the translation be carefully checked by bilingual medical experts to assure accuracy. Ample time for designing, reviewing, printing, and shipping of forms must be provided.

Regulatory

The starting point for meeting the regulatory requirements of all countries is consultation with the standard operating procedures of the sponsor and with GCP guidelines recognized worldwide. These documents provide the basis for generating a common set of investigator regulatory responsibilities. However, one should keep in mind that there may be specific requirements for certain countries. Listed below are some examples:

- Prior agreement from authorities via submission of comprehensive preclinical documentation, e.g. Clinical Trial Exemption (CTX), Investigational New Drug (IND).
- Permission from authorities to import a drug.
- Prescribed content and format of documents to be submitted to Ethical Review Committees/Institutional Review Boards.
- Requirements for patient information (written or oral).
- Obligatory drug labeling and procedures for drug labeling.
- Special procedures for AE reporting to national authorities.
- Liability insurance.

Some of these local requirements may be specifically addressed in the study protocol.

Informed Consent

The informed consent text should be, as far as possible, identical among the participating countries. The CMS is responsible for drafting the original form, then the subject must work closely with all CPLs to reach a consensus on a medically and ethically solid document that complies with the needs of all local ethical review boards and regulatory authorities. A clear and concise patient information sheet that may accompany the informed consent form should also be developed.

Clinical Quality Assurance

In the course of preparing a multinational clinical trial the coordination of quality assurance must be worked out early. This function may be assigned to the CQA manager of the coordinating country who will then work closely with the CQAs of participating countries and the CQA function in Germany. Details of this activity are provided in standard operating procedures.

Biometrics

The biometrician plays a pivotal role in the multinational clinical trial from the conceptualizing of the study protocol through the entire period of patient enrollment and finally

to the critical stage of data processing and analysis. Listed below are some of the more specific biometric activities:

- Development of the statistical plan including sample size calculation, statistical methods, and participation in the identification of the primary and secondary efficacy variables.
- Describe plans for interim analyses if any are to be performed.
- Coordinate development of the CRF.
- Participate in the development of the CRF Guide. (The guide is an indispensable tool that helps harmonize the multiplicity of methods and procedures that may be used in different countries. It also serves to remove ambiguities that may be linked to differences in language and medical culture inherent in each country.)
- Control for consistency of data recorded on the CRF. (Based on early review of a sample of CRFs from different countries, biometrics may identify inconsistencies in data recording which may stem from misunderstanding of CRF or the protocol itself. These must be rectified promptly and appropriate guidelines must be provided in the CRF Guide in order to avert further misunderstandings).
- Data management—very soon after patient enrollment starts, particularly for a complex study including numerous countries and centers, data management must rapidly identify inconsistencies in CRF data through well planned plausibility tests. These will inevitably lead to queries, even in a carefully monitored study, which must be clarified. The clarification process is sometimes a circuitous one from coordinator to CPL to study-site coordinator to investigator and may even have to be repeated more than once. This is very time-consuming and therefore, the earlier it is started the sooner the database may be finalized.
- Statistical analysis in the strict sense.
- Statistical component of the study reports.

Clinical Trial Supplies

The CMS is responsible for ordering clinical trial supplies. In a timely fashion, the CMS must obtain from participating countries all pertinent information on the legal requirements for importation of the study drug. This will ensure an early completion of order forms and the shipping of drug supplies on schedule. The following are important activities pertaining to this subject.

- Procedure for planning and ordering trial supplies. The plan for trial supplies is developed by the CMS in consultation with the International Clinical Project Manager at a very early stage. The plan must address bulk as well as all specially packaged materials including drugs used in positive control studies, test tubes, and even diluents or intravenous (IV) fluids when required.

When coordinating a multinational trial, the procedures to be followed are similar to those used for regional studies. However, considering the larger quantities of medication and materials often required, the coordinator must provide the Department of Clinical Supplies at Bayer with sufficient lead time.

- Label text—To facilitate preparation of labels at the local level, it is useful to have a detailed example of a label text in English. This may be translated and supplemented with any locally required labeling.
- Import license—At an early stage of trial preparation, the CMS must identify those countries that require importation licenses. Drug supplies may not be shipped until these are obtained. In Spain, for example, the study protocol must be approved by the Health Ministry and the Ethics Committee before an application for the import of test drugs may be filed. This stage may take 6 months or more.
- Randomization list—The coordinator must assure that the Department of Clinical Supplies will receive, on time, any applicable randomization lists.
- Bottlenecks—The coordinator should provide the Department of Clinical Supplies with a shipping list prioritized by country and center so that, in case of bottlenecks in the processing of orders, priorities are already established. This should be updated and revised as required.
- Tracking of supply requirements—The CMS is responsible for updating or revising orders based on the level of activity in participating countries (e.g., very slow or rapid enrollment, revised number of patients, new centers), or in case of an amendment to the study protocol (e.g., extension of the study).

Budget

It is no surprise that multinational clinical trials are expensive. The bulk of expense arises from the grants, which must be made to investigators, to assiduously carry out the trial in full compliance with the study protocol. However, other substantial expenses are incurred and include the following: overhead charges by hospital administration, which may exceed 50% of the investigator grant; payment to third-party providers of health care for special biochemical or other tests; investigator meetings; meetings and training sessions for investigator staff; international team meetings. More recently, charges for CROs have become prominent if the intramural capacity of the sponsoring company must be supplemented by extramural services to effectively monitor and rapidly process data from the trial. Other intramural costs include those associated with staffing for GCP, regulatory affairs, and those to support manufacturing, packaging, and shipping of study drug, control medications, and other materials.

In regard to the investigator grant for study, it is most desirable to provide investigators in each country with the same sum on a per patient basis. Occasionally, slight

differences may be necessary because of the individual needs of certain institutions. Early in the study planning, the CMS should develop a budget concept based on the requirements of the protocol and estimation of their current costs; this should constitute the framework for grant discussions with individual investigators. The contracts between sponsor and investigator within each country should be identical as far as possible.

There are certain costs associated with multinational trials that are sometimes subtle and not readily apparent beforehand. Included among these are the following:

- Local budget requirements which, in addition to grant support, must cover travel and other expenses of investigators when attending investigator and other meetings, and costs associated with logistical support of preparing and shipping any special biological specimens which may be required per protocol.
- Expenses incurred in the organizing of international activities, such as planning meetings, expert and investigator meetings, and costs of supporting very active extramural efficacy and safety review committees.

The costs for these functions must be planned for early and built into any overall budget for the trial.

DISCUSSION

The many advantages of a multinational clinical trial would seem to outweigh the potential disadvantages. The pros and cons for such an undertaking are listed in Table 1. Many clinical researchers feel that a multinational clinical trial should only be performed if it is not possible to successfully perform the trial in one country within an acceptable time frame. There are exceptions to this rule—for example, when it is an explicit objective of the trial to have investigators from a variety of countries gain experience with a new therapy, or if it is the intention of the sponsor to obtain data on drug efficacy and safety in a more internationally diverse cohort of patients.

Countries considered for participation in any multinational clinical trial should be carefully selected with the aim of minimizing differences in medical culture and practice. In addition, the resources and capacity of the sponsor's local medical departments must be carefully assessed.

Special attention must be paid to the appointment of the study coordinator who will be one the key individuals impacting on the quality and success of the trial. The coordinator should have clearly defined functions and responsibilities and be given sufficient authority and support by management to effectively carry out his/her assignment. The coordinator should be made responsible for the coordination of all tasks within the company and with participating country representatives who should functionally report to the coordinator regarding trial activities. The coordinator

Table 1 PROS/Requirements and CONS/Drawbacks for Multinational Clinical Trials

PROS/requirements

- Large sample size
- Increased speed of recruitment
- Broad acceptability of study results
- Broad impact on physician experience
- Increased access to patients with rare diseases
- Ample resources
- Simple trial design
- Simple, brief data collection sheet (CRF)

CONS/drawbacks

- Differences in
- Culture
- Medical training and practice
- Classification of diseases
- Prevalence of diseases
- Genetic Background of patients
- Therapy
- Language
- Diet, customs, religion
- Regulations (e.g., use of placebo)
- Writing numbers, dates and abbreviations
- Using central laboratories
- Interpretation of adverse events

must interact closely with the International Clinical Project Manager and usually with one or two senior and respected investigators who will play a leadership role in the trial.

The tasks and responsibilities of the individuals or committees described earlier—such as protocol development, drug supplies, regulatory, CQA, data management/statistics, safety, extramural review, data analysis, and manuscript preparation—must be clearly described and promulgated at an early stage of study preparation.

The study protocol and CRF should be made as clear as possible in order to prevent opportunities for misinterpretation which can easily occur given the different perspectives that investigators from various countries bring to the trial. This is a demanding task and starts with the individual who drafts the initial documents and proceeds to the next group of individuals to review them. As a general rule, before the documents progress to another level of review, there should be complete understanding and agreement among those who have already completed their review and provided input. This process may be tedious and time consuming but following this course will greatly assist in generating a final draft that is clear and unambiguous. Thus by the time investigators receive the protocol and CRF, the study concept and design have been thoroughly examined and sharply defined.

It is of paramount importance that input for both protocol and CRF be provided by the medical and biometrics representatives from all participating countries. These individuals bring not only their medical and biometric expertise to the subject, but also their international perspective, which will make both documents—particularly the CRF—more universal and user-friendly.

Thorough training of the intramural study team with respect to the protocol and CRF must be carried out. Any complicated or new procedures called for in the protocol should be explained by in-house experts so that staff are reasonably familiar with these before interfacing with the extramural investigator team. Training of the investigator teams should only be given after the intramural staff are thoroughly knowledgeable about both the protocol and CRF.

Occasionally, special medical/surgical procedures, which may not be standard to all centers, must be carried out as key components of a trial. These may also be the subject of special training seminars given by consulting experts. Training in these procedures will assist in assuring that all investigators bring to the study a high level of competence in these key procedures. This competence across study centers and countries will do much to minimize the center or country effects which must be statistically analyzed at the end of the trial.

Procedures for quality assurance should also be agreed upon in advance. For example, compliance with protocol, procurement of informed consent, accurate completion of CRFs, reporting of all serious or unexpected AEs, and availability of source data for review by study monitors must be assured. The sponsor may identify a single individual who will be responsible for coordinating all CQA activities with the local CQA representatives.

Early during patient enrollment, the trial coordinator with other clinical colleagues will team up with the biometrics group to define the approach to data analysis and table set generation. This is a very challenging and time-consuming task, but a satisfying one because it begins to address the outcome of the trial and therefore the fruits of one's labor.

Considering the high cost of a multinational trial compared to the cost of a multicenter trial performed in one country—in terms of translations, struggles to harmonize, logistics, communications, organizing of meetings, and travel—once a multinational trial is initiated the sponsor should make every effort to achieve successful completion. It should be borne in mind, however, that even if all of the preparatory and organizational aspects of a trial are performed perfectly, for the trial to succeed, it must have the full commitment and motivation of all of the investigators. Although the scientific task itself may be motivating the investigators, commitment must be sustained throughout the study. This may be encouraged by meaningful communications among the members of the study group particularly on such aspects as study status, events, actions by individual committees, results (even before the end of the trial, without code breaking, for example on the demographics

or other features of the patient population under study), and scientific updates in the relevant therapeutic areas. Such communications can be achieved through monitoring contacts, newsletters, and importantly, through investigator meetings. These communications should not be restricted to principle investigators alone but should include assistants and other pertinent supporting research staff.

CONCLUSION

The increased use of multinational clinical trials in Phase IIB and Phase III of clinical drug development or following the introduction of a new drug demonstrates that the advantages of access to a larger number of patients and usually a more rapid recruitment, and earlier completion of the trial, and the experience gained from use of the drug in differing patient populations, outweigh the disadvantages or drawbacks of varying medical practice and culture and the increased costs associated with the trial. The sometimes perceived glamor of such an undertaking should not distract from the careful monitoring and meticulous attention that must be devoted to detail in the overall management of the trial.

It should be noted that there are still many scientific/practical issues associated with multinational clinical trials remain unsolved. These issues include, but are not limited to, translation/back translation of the informed consent form and case report forms, sample size requirements in specific countries, the use of central laboratory, and possible treatment-by-country interaction due to difference in ethnic factor.^[4,5]

Multiple Comparisons

Abstract

Efficacy and safety claims of an experimental drug are never based on one endpoint, but on several endpoints. This entry reviews the importance of multiple comparisons among treatments in clinical research.

INTRODUCTION

Generally, a phase II/III trial involves collecting data for evidence to show the efficacy and safety of an experimental drug. The integrity of this evidence relies heavily on such factors as the design, the patients recruited, the overall conduct of the study, and the appropriateness of the endpoints and the analysis. Descriptions of these factors must be clearly specified a priori in the protocol, as required by the regulatory guidelines.

Efficacy and safety claims of an experimental drug are never based on one endpoint, but on several endpoints. For example, in a trial involving patients with schizophrenia, a set of efficacy endpoints may include more than one derived measure from the Positive and Negative Symptom Scales (PANSS) and Clinical Global Assessment Scales (CGI-severity and CGI-improvement). Also, for most of the trials, a safety claim is based on adverse events, vital signs, laboratory measurements, and electrocardiogram. In addition to several endpoints, most of the phase II/III trials are typically comparative trials—comparison against placebo or an active therapy, or dose-response trials that involve more than one dose of the experimental drug. There is also a time factor that enters into the overall equation; viz., patient data for various endpoints and doses are collected across several time points in a longitudinal fashion. It is now not difficult to imagine the dimensionality of the accumulated data collected with one overall objective of showing that the drug is either efficacious or safe or both.

OVERVIEW

Statisticians play an important role in assuring their clients—the clinicians—that the design and the methods chosen are appropriate and most sensitive to the primary questions that are asked in the protocol. If the trial is an exploratory one, then it is typical to present and interpret the data using data summaries such as means and standard

deviations, without straying into any inferential procedures. For a confirmatory trial, final conclusion about the success or failure of the study is generally based on statistical inference and a presentation of the overall p -value. With the unavoidable multiplicity in a trial such as just described, if the overall conclusion is based on several comparisons, it can then result in the presentation of several p -values from various statistical tests. There is always some chance that not all of these tests would result in a statistical significance, typically considered as $p \leq 0.05$.

Suppose, in a confirmatory pivotal trial with three doses of an experimental drug and a placebo with one primary endpoint, that out of three pairwise comparisons with placebo, only two yield significant results. For this example, suppose we would like to make an overall claim that the trial has proven the efficacy of the drug. Regulators (such as the U.S. Food and Drug Administration, FDA) may not accept as evidence of efficacy, especially if it is not specified a priori, which comparison is more important than the other. From their perspective, regulators are not comfortable with an inefficacious drug reaching the market, compared with an efficacious drug not reaching the market. That is, a false-positive result is more of an issue to the regulators; this idea will be covered further in the section “Error Rates and Need for Multiple Comparisons.”

ERROR RATES AND NEED FOR MULTIPLE COMPARISONS

When there is more than one treatment, an overall F -test can be performed to determine whether there is any difference in the treatments. If the overall F -test is significant, then individual comparisons between the treatments, generally pairwise comparisons, are carried out to investigate which treatment is different from what. At this point, it must be made clear that considering these pairwise comparisons only if the overall F -test is significant might be erroneous.^[1] Suppose, in a trial involving three doses of an

experimental drug (low, medium, and high) and a placebo, that there are six possible pairwise comparisons in this trial (or experiment). In general, if there are k treatments, then there are $k(k-1)/2$ possible pairwise comparisons.

A *comparisonwise error rate* (CWE) is a type I error rate for each comparisons; that is, it is the probability of erroneously rejecting the null hypothesis between treatments involved in the comparison. On the other hand, an *experimentwise error rate* (EWE, or *familywise error rate*, *FWER*) is the error rate associated with one or more type I errors for all comparisons included in the experiment. When multiple statistical tests are performed using the same data set, the *EWE* can be much larger than the significance level associated with each test itself. For illustration, assume that $P\{\text{type I}\} = \alpha$ for each test or comparison. Then, for k comparisons,

- $\text{CWE} = \alpha$
- $\text{EWE} = 1 - (1 - \alpha)^k$

To illustrate the inflation of the *EWE*, these rates can be expressed in numbers as (with $\alpha = 0.05$):

k	CWE	EWE
1	0.05	0.05
5	0.05	0.25
10	0.05	0.40
20	0.05	0.64
50	0.05	0.92

As can be seen in the table, even with $k = 5$ comparisons, the *EWE* increases to 25%, which may make the overall conclusion based on these $k = 5$ comparisons questionable. A property that is generally required is the strong control of the *FWER*, that is, the probability of making one or more errors on the whole of the considered hypotheses Marcus et al.^[2] On the other hand, a weak control of the *FWER* means simply controlling the α for the global test. Although the latter is a more lenient control, it does not allow the selection of active variables because it simply produces a global p -value that does not allow interesting hypotheses to be selected, so the former is usually preferred because it makes inference on each (univariate) hypothesis.

Several procedures have been suggested for controlling *FWER*. Some authors have grouped the most commonly used *FWER* multiple comparison methods into three categories: (i) single step methods (e.g., Bonferroni correction), (ii) step-down methods (e.g., Holm's method), and (iii) step-up methods (e.g., Hochberg's method).

An alternative approach to multiplicity control is given by the False Discovery Rate (FDR). This is the maximum proportion of type I errors in the set of elementary hypotheses. The *FWE* guarantees a more severe control than the *FDR*, which in fact only controls the *FWE* in the case of global null hypotheses, that is, when all involved hypotheses are under the null.^[3]

Preference of choosing *FDR* over *FWER* for controlling multiplicity depends on the experimental hypotheses. In confirmatory studies, it is usually better to strongly control the *FWER*, which will guarantee an adequate inference when it is preferable not to commit even a single error. In the case of exploratory studies or experiments involving large number of hypotheses (e.g., micro-array data), the aim is to highlight a pattern of potentially involved variables. In such cases, requiring that not a single error be made may be too stringent, and as a result, *FDR* would appear to be a more reasonable approach. On the other hand, Huang and Hsu^[4] provide arguments explaining why controlling *FDR* is inappropriate in clinical trials.

More recently, Storey et al.^[5] have developed a new procedure called the Optimal Discovery Procedure (ODP) to deal with simultaneous significance testing. The Neyman-Pearson lemma has been a standard in providing a simple rule for optimally testing a single hypothesis when the null and alternative hypotheses are known. The majority of the research involving strategies extending a single testing procedure to multiple tests tends to be based on p -values that are calculated from individual tests as a mean to control *FWER* or *FDR*. The ODP method proposed by Storey provides a platform where one can borrow strength from multiple tests to improve the performance of simultaneous testing. This is very similar to shrinkage estimation in which one borrows strength across point estimates to improve the overall performance.

Descriptions of some of the multiple comparisons procedures as well as the control of *FDR* are provided below:

DESCRIPTION

P-Value Based Procedures

The p -value based procedures can be classified into single-step procedures and stepwise procedures. Single-step procedures (or global test procedures)—for example, procedures based on Bonferroni or Sidak inequality and their modification—test each null hypothesis of interest independently without referring to other hypotheses, and thus the order in which the null hypotheses are examined is not important. In contrast, stepwise procedures, such as the Holm procedure, the Hochberg procedure, and the Hommel procedure, test each hypothesis separately, and the decision to reject or accept is made by implication in a sequential manner. It is generally true that stepwise procedures are more powerful than single-step procedures in the sense that they reject more null hypotheses without inflating the *FWER*.

Global Test Procedures

Suppose the trial objective is to determine the overall treatment effect on a primary endpoint. In this situation, it is

appropriate to apply a global test procedure (as described below), even though other procedures (such as step-down approach) can also be applied on an endpoint basis. Some of the global test procedures include likelihood ratio (LR) test, Ordinary Least Squares (OLS) and Generalized Least Squares (GLS) tests, and Bonferroni and Simes approaches. When there are multiple groups (e.g., treatments), at the conclusion of a global test it is imperative to perform all-pairwise comparisons (described below).

All Pairwise Comparisons

Assume that there are k treatment means (or LSMEANS in SASTM terminology), $\bar{y}_1, \bar{y}_2, \dots, \bar{y}_k$, and let s^2 be an estimate of the variance, typically obtained from an analysis of variance (ANOVA) table. In the case of an unbalanced one-way model, with n_i observations for treatment i ,

$$\bar{y}_i = \frac{\sum y_{ij}}{n_i}$$

$$s^2 = \frac{\sum \sum (y_{ij} - \bar{y}_i)^2}{\sum (n_i - 1)} \quad (1)$$

where $v = \sum (n_i - 1)$ is the degrees of freedom associated with the estimate s^2 .

Fisher's Least Significant Difference

Fisher's least significant difference (LSD) method is a two-step process. As indicated in section "Error Rates and Need for Multiple Comparisons," one starts with an overall F -test for testing the equality of treatment means, $H_0: \mu_1 = \mu_2 = \dots = \mu_k$. If H_0 is not rejected, then no further steps are taken. Otherwise, this method concludes that the treatment means μ_i and μ_j are different, for every $i \neq j$, if

$$|\bar{y}_i - \bar{y}_j| > t_{\alpha/2}(v) \left[s^2 \left(n_i^{-1} + n_j^{-1} \right) \right]^{1/2} \quad (2)$$

where $t_{\alpha/2}(v)$ denotes a critical value for the t -distribution having v degrees of freedom and an upper-tail probability of $\alpha/2$.

This two-step Fisher's LSD procedure, also known as the *protected LSD method*, controls the CWE at the level α if the overall null hypothesis is true. If the overall null hypothesis is false, then it does not control the CWE unless $k \leq 3$. The unprotected LSD procedure is used with a significance level that is chosen to control the EWE; that is, the rate used to assert the simultaneous correctness of the comparisons is of no consequence. If a moderate or large number of comparisons ($k > 3$) is to be carried out, then neither of the LSD procedures is recommended, and the Bonferroni method can be considered as an alternative.

Bonferroni Method

The *Bonferroni method* uses the Eq. inequality (2) with a CWE of α/m , where α is the desired EWE and m is the number of pairwise comparisons that are to be carried out within the experiment. This procedure is not recommended if there is a large number of pairwise comparisons, which can render the CWE too small to be of any value as α/m becomes small when m is increased. In such situations, multiple range tests provide some alternatives, some of which are discussed next.

Tukey's Multiple Range Test

The method suggested by Tukey controls the EWE incurred in testing for treatment differences, especially when the averages involved in those differences are based on the same number of observations, that is, when they are taken in pairs. Using this test, we can declare the two means $\bar{y}_i$ and $\bar{y}_j$ to be significantly different if

$$|\bar{y}_i - \bar{y}_j| > q(\alpha, k, v) \left\{ s^2 \frac{(n_i^{-1} + n_j^{-1})}{2} \right\}^{1/2} \quad (3)$$

where $q(\alpha, k, v)$ is the "studentized range statistic," k is the number of averages being compared, s^2 is the mean squared error (MSE) from the ANOVA model with v degrees of freedom, and α is the EWE. Tables of critical values for the studentized range statistic are widely available.

This multiple range test suggested by Tukey can also be used to construct simultaneous confidence intervals on all pairs of mean differences $\mu_i - \mu_j$, and it has been shown that the confidence intervals have a confidence coefficient $100(1 - \alpha)\%$ collectively; that is, 4

$$P \left\{ \mu_i - \mu_j \in \bar{y}_i - \bar{y}_j \pm |q| \left[s^2 \frac{(n_i^{-1} + n_j^{-1})}{2} \right]^{1/2} \text{ for all } i \neq j \right\} = 1 - \alpha \quad (4)$$

Duncan's Multiple Range Test

For comparison of pairs of treatment means, Duncan has developed a test, called a *multiple range test*; its CWE is a function of the number of comparisons. It is a good compromise between Fisher's LSD and Tukey's multiple range test, but it does not control the CWE. To use this test, first the treatment means, obtained from a balanced design with a sample size n , are arranged in ascending order. The criterion is to conclude that the largest and smallest of the treatment means, $\bar{y}_i$ and $\bar{y}_j$, are significantly different if

$$|\bar{y}_i - \bar{y}_j| > q(\alpha_p, p, v) \left\{ \frac{\text{MSE}}{n} \right\}^{1/2} \quad (5)$$

where p = number of averages, $q(\alpha_p, p, v)$ is the critical value from the “studentized range statistic” with an EWE of α_p , and MSE is the mean squared error with v degrees of freedom. When α is the CWE, then α_p is related to α as $\alpha_p = 1 - (1 - \alpha)^{p-1}$.

Holm's method

Holm's^[6] sequentially rejective procedure represents an example of a step-down method. Holm's method improves the sensitivity of Bonferroni's method to detect real differences. The method sequentially contrasts ordered unadjusted p -values with a set of critical values and rejects a null hypothesis if the p -value and each of the smaller p -values are less than their corresponding critical values. The increase in power with Holm's approach is substantial when some null hypotheses are rejected with a high probability while the remaining p -values are compared with less stringent critical values and provides a strong control of the FWER.

Simes Method

With the Simes Method, one would reject the global null hypothesis if $p_{(i)} \leq \alpha/m$, for at least one $i = 1, 2, \dots, m$. The adjusted p -value for the global hypothesis is $p^* = m \cdot \min\{p_{(1)}/1, \dots, p_{(m)}/m\}$. Simes method provides an improvement over Bonferroni approach in controlling the global type I error rate under independence. Recent research in this area indicates that the Simes method does provide satisfactory control of the FWER but can sometimes exceeds α .^[7] Finally, Simes method cannot be used to make inferences on individual hypothesis, since it test only the global hypothesis.

Other Tests

There are other tests available for pairwise comparisons. These are not discussed here, but detailed discussions on these procedures are available in the literature.^[1]

Multiple Comparisons with a Control

In many clinical studies, when there are several treatment groups (e.g., multiple doses of an experimental drug) and a control group, the primary objective specified in the protocol may dictate comparison of the treatment group against the control group, but within-treatment group comparisons may not be required. For example, if the interest is only to show that the new therapy is “better” than no therapy (placebo), then there is no need to make comparisons between the dose groups of the new therapy. Comparisons of such types are known as *multiple comparisons with a control*.

Dunnett's test is the most popularly used multiple comparison procedure for comparison against a control.

Dunnett's Test

Suppose the $k - 1$ treatment groups are given as μ_i , $i = 1, 2, \dots, k - 1$, and the control group is denoted as μ_k . Furthermore, the treatment groups are modeled in terms of a balanced one-way model as

$$y_{ij} = \mu_i + \varepsilon_{ij}, \quad i = 1, 2, \dots, k; \quad j = 1, 2, \dots, n \quad (6)$$

Assume that the error terms ε_{ij} are normally distributed with mean 0 and unknown variance σ^2 . Eq. 1 can now be used to estimate μ_i and σ^2 for this balanced model.

Dunnett's method provides both one-sided and two-sided simultaneous confidence intervals for $\mu_i - \mu_k$.^[1] For the one-sided alternatives, the lower bound of the confidence interval is given as

$$\mu_i - \mu_k > \hat{\mu}_i - \hat{\mu}_k - T \hat{\sigma} \sqrt{\frac{2}{n}}, \quad \text{for } i = 1, 2, \dots, k - 1 \quad (7)$$

where $T = T_{k-1, v}(\{\rho_{ij}\})(\alpha)$ is solved using the following equation:

$$\int_0^\infty \int_{-\infty}^\infty [\Phi(z + \sqrt{2}Tu)]^{k-1} d\Phi(z) \gamma(u) du = 1 - \alpha \quad (8)$$

In Eq. 8, γ is the density of $\hat{\sigma}/\sigma$, Φ is the distribution function of the standard normal, and T depends only on α , k , $v = k(n - 1)$, and $\rho_{ij} = 1/2$ for all $1 \leq i \neq j \leq k - 1$. Also, ρ_{ij} is the correlation coefficient of the estimators $\hat{\delta}_i = \hat{\mu}_i - \hat{\mu}_k$ ($1 \leq i \leq k - 1$). It is widely known^[8] that $T = T_{k-1, v}(\{\rho_{ij}\})(\alpha)$ are the critical points from the distribution of the random variable $\max T_i$, where $T_1, T_2, \dots, T_k$ have a multivariate t -distribution with v degrees of freedom and correlation matrix $\{\rho_{ij}\}$; its tabulated values are widely available for the case $\rho_{ij} = \rho$.

For two-sided simultaneous confidence intervals, $\hat{\mu}_i - \hat{\mu}_k \pm |h| \hat{\sigma} \sqrt{2n}$, the solution to $|h|$ is obtained through the equation

$$\int_0^\infty \int_{-\infty}^\infty [\Phi(z + \sqrt{2}|h|t) - \Phi(z - \sqrt{2}|h|t)]^{k-1} d\Phi(z) \Upsilon(t) dt$$

In other words, $|h|$ are critical points from the distribution of $\max |T_i|$. For the unbalanced case, tabulation of the critical values may be impractical in many cases. But for some special correlation structures, the integration in Eq. 8 can be simplified to produce iterative solutions. For example, in the case of an unbalanced one-way design, $\rho_{ij} = \lambda_i \lambda_j$ ($1 \leq i \neq j \leq k - 1$), where $\lambda_i = (1 + n_k/n_i)^{-1/2}$ for $i = 1, 2, \dots, k - 1$; tables are available for this case.^[8]

Other Tests

Other procedures, such as step-up and step-down procedures, available for multiple comparisons against a control^[1] are not discussed here.

Multiple Comparisons in Dose-Finding Studies

Dose-response studies are performed to evaluate the relationship between the effect (both efficacy and safety) and the dose and to evaluate the recommended dose regimen and frequency. In such studies, several doses of the experimental drug are compared against the zero-dose (or placebo) control. If there is no monotonicity assumed in the effect (that is, group means are not ordered), then Dunnett's test is recommended to compare the group means against placebo. But if the group means are expected to follow an increasing or decreasing order, then there are several procedures available for comparing the doses against placebo. One of the main benefits of some of these procedures is the control of familywise error rate.

Dose-response studies may have multiple endpoints, e.g., primary and secondary endpoints. Under this scenario, inference on the secondary endpoints is performed only after confirming efficacy in the primary endpoint at that dose. This ordering guides the selection of test statistics for each intersection hypothesis in closed testing. Liu et al.^[9] provide a different perspective showing that ordering guides the partitioning of the parameter space in using the partitioning principle to construct multiple tests that control the appropriate FWER.

Closed Test Procedures

Suppose there is a family of hypotheses denoted by $\{H_i, 1 \leq i \leq k\}$ and its closure is represented by taking all nonempty intersections $H_p = \bigcap_{j \in P} H_j$ for $P \subset \{1, 2, \dots, k\}$. A *closed testing method*^[2] asserts that any hypothesis H_p is rejected if and only if every H_Q is rejected by its associated α -level test for all $Q \supset P$, assuming that an α -level test for each hypothesis H_p is available. For tests of this type, Marcus et al.^[2] showed that it controls the type I familywise error rate. In order to use this method, if we have α -level tests individually for each H_p , then they can be applied in a step-down manner. A simple example is provided by a modified Dunnett's test.

Suppose that, in a dose-response study with several doses of an experimental drug and a placebo, it is assumed that the primary objective is to make one-sided comparisons with placebo. For this example, consider a family of hypotheses: $\{H_i : \mu_i - \mu_k \leq 0 (1 \leq i \leq k-1)\}$ against upper one-sided alternatives, where placebo is the k th group. Further, let us assume that the treatment groups have the same size n and that the number of patients in placebo is n_k , and let $\rho = n/(n + n_k)$. The step-down procedure is carried out as follows:

- Calculate T_p , the t -statistics for $1 \leq i \leq k-1$, and let the ordered t -statistics be $T_{(1)} \leq T_{(2)} \leq \dots \leq T_{(k-1)}$ with their corresponding hypotheses denoted as $H_{(1)}, H_{(2)}, \dots, H_{(k-1)}$.
- Reject $H_{(j)}$ if $T_{(i)} > T_{j,v,p}(\alpha)$ for $i = k-1, k-2, \dots, j$. If $H_{(j)}$ is not rejected, then conclude that $H_{(j-1)}, \dots, H_{(1)}$ are also to be retained.

This step-down version of Dunnett's test is more powerful than the test given in Eq. 7, which is based on a single critical value.^[2]

Partitioning Principle

Similar to the closure method described above, the partitioning principle partitions the parameter space into disjoint sets with or without some logical ordering of the hypotheses. Inferential tests are then performed sequentially at different partitioning stages, and the inferential testing stops upon failure to reject a given null hypothesis at the pre-determined partitioning stages. Because the sets of null hypothesis are disjointed at most one set can be true. As a result, even though no multiplicity adjustment is needed, the probability of rejecting at least one true null hypothesis is at most α . Huang and Hsu^[4] have shown that both Holm's method and Hochberg's approach to multiple testing, viewed as step-down and step-up versions of the Bonferroni test, are special cases of testing that uses partitioning principle. They have also shown geometrically that Hochberg's step-up method "cuts corners" off the acceptance regions of Holm's step-down method by making assumptions on the joint distribution of the test statistics.

Inference via the partitioning principle uses the data to decide in which subspaces the true parameter may lie. It has been successfully applied to derive practically useful methods for various areas, including clinical trials. However, the formulation of disjointed sets of hypotheses may be cumbersome when the number of endpoints is moderately large. Moreover, similar to the closure method, confidence intervals on the parameters are generally unavailable.

Other Tests

Other multiple test procedures for dose-finding studies are described in Refs. [10,11]

DESIGN ISSUES

Active Control Studies

In many areas of clinical research (e.g., anti-infectives), standard therapies (positive or active controls) are commonly available in the market. Inclusion of one or more doses of the positive control would serve as reference standard for efficacy comparisons with the experimental

drug, while comparison with placebo would validate the clinical trial. In other words, it would serve to differentiate between an “ineffective” drug vs. an “ineffective” study.

When a trial involves one or more doses of an experimental drug, placebo, and one or more doses of an active control, always the first dilemma is to establish a family of hypotheses a priori in the protocol. Based on the study design and various underlying hypotheses, strategies should be explored for testing various hypotheses. One such set of hypotheses, {drug vs. placebo} and {positive control vs. placebo}, would help to conclude whether both the drug and the positive control are superior to placebo. For each one of these hypotheses, multiple comparison procedures would then have to be proposed in the protocol, depending on the objective of either controlling *comparisonwise* or *familywise* error rate.^[12]

Sample Size

As study designs in most of the clinical trials involve an ANOVA or an analysis of covariance (ANCOVA) model, it is not uncommon to perform sample size calculations based on an overall *F*-test, which may not be appropriate if the primary objective involves multiple comparisons. When multiple comparisons are involved, another approach used is to adjust the Type I error level with a Bonferroni correction. Again, this may lead to more patients than what is actually required. Hsu^[13] suggests a confidence interval approach as follows: Given a confidence interval approach with level $1 - \alpha$, do the sample size computations so that with a prespecified power $1 - \beta (< 1 - \alpha)$, the confidence intervals will cover the true parameter value and be sufficiently narrow. Technical details for exact sample size computations are given in [Appendix C](#) of Hsu's excellent textbook.^[1] Certain computer software, including SASTM procedures, is also available for sample size computations that require adjustment for multiple comparisons and multiple tests.^[14]

CONCLUSION

Multiple comparisons are commonly encountered in clinical research. Multiple comparisons may involve pairwise comparisons among treatments or multiple comparisons with a control when there are more than two treatments in the study. In this case, statistical methods for controlling error rates such as CWE or EWE or FDR are necessary for multiple comparisons. In practice, closed test procedures are useful for addressing multiple comparisons in dose-finding studies. If there are large number of tests are involved (e.g., safety data), then it would be worthwhile to investigate controlling the false discovery rate (FDR).

It should be noted that FDA circulated a draft guidance on multiple endpoints in clinical trials for comments in

January 2017.¹⁵ This draft guidance, when finalized, will represent FDA's current thinking about the problems posed by multiple endpoints in the analysis and interpretation of study results and how these problems can be managed in clinical trials for human drugs, including drugs subject to licensing as biological products.

ACKNOWLEDGEMENTS

Minor updates have been made by the Editor-in-Chief in order to reflect developments since publication of the *Encyclopedia of Biopharmaceutical Statistics, Third Edition*.

Multiple Endpoints

Mario Comelli

Università di Pavia, Pavia, Italy

Abstract

The aim of this entry is to give a synthetic account of several actually known methods of analysis of multiple endpoints.

INTRODUCTION

A common problem arising in medical research is that of comparing some groups of patients (for instance, the arms of a clinical trial) based on multiple outcome measures called *endpoints*, all of which must be considered of primary importance and have no hierarchical structure. The aim of this entry is to give a synthetic account of several actually known methods of analysis of multiple endpoints. Each method is described with its merits and the situations where it is most appropriate. The procedures of application will be detailed wherever possible. However, sometimes the reader will be referred to the original article for the steps of computation. Most of the published material on the topic concerns the comparison of two groups. So for most of this entry, only the comparison of two arms of a study will be considered. They will be identified as experimental and control. Consistent with the informative nature of this entry, mathematical formalism will be kept to a minimum.

In the analysis of a multiple endpoint study, two types of questions are possible:

1. Are there any endpoints for which the experimental treatment is more effective than the control (or vice versa)? Which are these endpoints?
2. Does the combined evidence of all endpoints support the global superiority of the experimental treatment, even if no clear conclusions can be drawn for any determined endpoint?

By answering the first question, one can often answer the second question as well. Indeed, if one proves that the experimental treatment is more effective than the control for determined endpoints, and no less effective for the others, one has also proved that the treatment is globally superior to the control. The reverse, however, is not true.

NOTATION

C	is the control treatment
T	is the experimental treatment.
k	is the number of endpoints.
n_T and n_C	are the numbers of subjects in the T and C samples, respectively.
S_i or s_i	is a test statistic that compares the effect of T and C on the i th endpoint. (Uppercase indicates a random variable, lowercase an observed value.)
P_i (or p_i)	is the unadjusted P -value of the univariate test on the i th endpoint. (Uppercase indicates a random variable, lowercase an observed value.) P_i does not take the multiplicity of endpoints into account. Therefore P_i (or p_i) is called <i>raw</i> or <i>nominal</i> .
P_{ia} (or p_{ia})	is the P -value of the test on the i th endpoint adjusted by taking into account the multiplicity of endpoints. Therefore P_{ia} (or p_{ia}) is called <i>adjusted</i> .
S or s	is a test statistic that compares the effect of T and C simultaneously on all endpoints.
P or p	is the P -value of the global comparison, testing the global difference of the effect of T and C on all endpoints, without identifying the endpoints where the difference is “significant.”
H_0	is the global null hypothesis. It states that the difference of effect to T and C is zero on all endpoints.
H_{0i}	is the null hypothesis that the effect of T and C on the i th endpoint is the same.
$\sim H_{0i}$	is an alternative hypothesis to H_{0i} and to H_0 . It states that the effect of T and C on the i th endpoint is not the same; it is the complement of H_{0i} .
m	is the number of true H_{0i} in the trial.
$\mathcal{P}(E)$	is the probability of an event E .

$\bar{E}$	is the complementary event of E .
FWER	is the familywise error rate in the strong sense. It is the probability of rejecting one (or more) true null hypotheses when a mixed set (a family) of true and false null hypotheses is tested. In other words, it is the probability of making at least one Type I error in the whole set of comparisons.
α_c	is the Type I error probability required for each comparison to obtain $\text{FWER} = \alpha$.

If not otherwise specified, all P -values are taken two-sided.

IDENTIFICATION OF THE ENDPOINTS WHERE T IS MORE EFFECTIVE THAN C

Identifying the endpoints affected by T is a multiple comparison problem. It requires the test of one hypothesis for each endpoint. Because of the many hypotheses tested, the main difficulty is to avoid the multiple testing bias without losing too much power. There are different types of methods to attain this aim. Some of them compute adjusted P -values using the p_i s obtained via the univariate test (even if the tests are different for different endpoints). These methods can be also used by the reader of a scientific paper reporting p_i s. Their drawback is that they are often difficult to apply to the computation of confidence intervals or of the required sample size of a clinical trial.

Some other procedures use the distribution or at least the correlation matrix of the endpoints under H_0 . They either postulate a known distribution or empirically estimate it. This type of technique has some specific developments for binary endpoints.

P -Value–Based Techniques

The simplest technique of this type is the *Bonferroni correction*, which consists of multiplying all p_i s by k . The p_{ia} s so obtained are then compared to the chosen Type I error probability: α (e.g., 0.05). This technique keeps $\text{FWER} \leq \alpha$. Therefore from the p_{ia} s, one can draw inferences concerning each single endpoint exactly as if it were the only one tested. The Bonferroni method is based on the Bonferroni probability inequality,^[1] which is true for every set of k events E_j :

$$1 - \mathcal{P}\left(\bigcap_{j=1}^k E_j\right) \leq \sum_{j=1}^k \mathcal{P}(\bar{E}_j) \quad (1)$$

Let us consider a family of k endpoints. Let E_j be the event that the test statistic S_j of the j th endpoint assumes a more probable (or with a higher probability density) value than a certain s_j having P -value p . Then, the left-hand side is the probability of obtaining, at least once, a P -value equal to or lower than p in the whole set of k comparisons.

Let $\bar{E}_j$ be the complement of E_j . The P -value p of the statistic s_j , by definition, is the probability of obtaining a value of S_j equally probable to or less probable (or with an equal or lower density) than s_j if H_{0j} is true. Therefore, if H_{0j} is true, $\mathcal{P}(\bar{E}_j) = p$. Moreover, if there are $m \leq k$ true H_{0j} s, then the probability of all the corresponding events $\bar{E}_j$ is equal to p . Therefore applying the Bonferroni inequality only to the endpoints unaffected by the treatment, one obtains

$$1 - \mathcal{P}\left(\bigcap_{j=1}^m E_j\right) \leq mp \leq kp \quad (2)$$

Now one can assume p as equal to the observed raw P -value p_i of a certain H_{0i} . Subsequently, the inequality states that the probability of obtaining once or more, for the set of m true H_{0j} s, a test statistic S_j equally probable to or less probable (or with an equal or lower density) than a value s_j having P -value p_i is lower than kp_i . By a slight generalization of the definition of P -value, we call that quantity p_{ia} , i.e., the P -value of the i th endpoint, computed by taking into account the error probability of all the comparisons. In other words, p_{ia} is the P -value adjusted for multiplicity.

Another very simple formula for the computation of adjusted p_{ia} s is obtained under the condition that the endpoints are stochastically independent. It can be derived as follows: The probability of obtaining, for all P_j s of the m true H_{0j} s, values larger than p_i is $(1 - p_i)^m$, under independence. Therefore the probability of obtaining for at least one P_j corresponding to a true H_{0j} a value equal to or smaller than p_i is

$$1 - (1 - p_i)^m \leq 1 - (1 - p_i)^k \quad (3)$$

So one can obtain $p_{ia} = 1 - (1 - p_i)^k$.

Many improvements to the Bonferroni correction to test single endpoints have been proposed; they obtain a greater power by taking into account all the p_i 's, instead of just the one to correct.^[2–4] Some of these are very simple to use. The general logic of Holm's step-down technique^[2] is as follows: Put the p_i s in increasing order and adjust the smallest via the Bonferroni correction. If the p_{ia} so obtained is larger than the chosen Type I error probability α , retain all H_{0i} s. If, on the contrary, its value is smaller than α , then reject the corresponding H_{0i} . This H_{0i} is then to be excluded from the set of possible true null hypotheses. Therefore adjust the second smallest p_i by multiplying it by the correction factor $k - 1$. Indeed, recall from Eq. (2) that to adjust p_i , it is enough to multiply it by the number of true H_{0j} s; now, after the rejection of one hypothesis, we know that the number of true H_{0j} s is not larger than $k - 1$. If the second p_{ia} is larger than α , then retain the corresponding hypothesis and all those having p_i s. If it is equal or smaller than α , then reject the corresponding H_{0i} , and go on with the same logic to compute the third p_{ia} by multiplying the third smallest p_i by $(k - 2)$. Compare

the third p_{ia} with α , and so on. The procedure stops when a p_{ia} turns out to be nonsignificant: then retain the H_{oi} under scrutiny and the remaining H_{oi} s.

Hochberg's step-up procedure^[4] theoretically requires the stochastic independence of the test statistics used to detect the effect of T on different endpoints. However, simulation results^[5,6] confirm that it is conservative, i.e., it keeps the FWER smaller than the declared α , also when the test statistics are positively correlated. Hochberg and Rom^[7] study its behavior when the p_i s are obtained from Z-tests (the simplest test for Gaussian endpoints with known variance). They theoretically prove that Hochberg's procedure is conservative when the test statistics are either positively correlated or examined by two-sided tests. When Z values are negatively correlated and the tests are one-sided with $\alpha = 0.05$, the theoretical upper bound of FWER is 0.0525.

The derivation of Hochberg's method is rather complex and is explained in three papers.^[3,4,8] However, its application is simple: arrange the p_i s in decreasing order. If the largest p_i is equal to or smaller than the required α , all the H_{oi} s are rejected. Otherwise, multiply the second largest p_i by 2: If the product is equal to or smaller than α , reject the corresponding H_{oi} and all the H_{oi} s with smaller p_i s. Otherwise, retain the corresponding H_{oi} , multiply the third largest p_i by 3, and compare it with α . If it is equal to or smaller than α , reject the corresponding H_{oi} and all the H_{oi} s with smaller p_i s. If the value is larger, then retain the corresponding H_{oi} , and so on. The procedure continues until an H_{oi} is rejected; then all H_{oi} s with a smaller p_i than the first rejected H_{oi} are rejected as well. The p_{ia} of each endpoint is obtained from the corresponding raw p_i multiplied by its rank (in decreasing order). If this product is larger than the p_{ia} computed from the proceeding p_i , it is substituted by the preceding p_{ia} . This is carried out to account for the nonincreasing order of the p_{ia} s.

Hochberg's technique is always more powerful than Holm's. For an example of its application to a real clinical trial data as compared to other adjustment techniques, see Ref. [9].

Hochberg and Benjamini^[10] improved Hochberg's method using an estimate of the number of the true H_{oi} s in the trial. The value of is obtained by applying the graphical technique of Schweder and Spjøtvoll^[11] (described in the section "Inferring the Global Superiority of the Treatment from the Combined Evidence of All Endpoints") to two-sided p_i s. At the beginning of the procedure, arrange the p_i s in decreasing order and retain all H_{oi} s having a p_i larger than α . Let a be the number of accepted H_{oi} s. Then multiply the largest p_i of the H_{oi} s not retained by the smaller of the values $a + 1$ and $\hat{m}$. If the product is smaller than α , reject the corresponding H_{oi} and all the ones with smaller p_i s. Otherwise, retain the corresponding H_{oi} and multiply the next p_i by the smaller of the values $a + 2$ and $\hat{m}$. If the product is smaller than α , reject the corresponding H_{oi} and all the H_{oi} s with smaller p_i s. Otherwise, retain the

concerned H_{oi} and multiply the next p_i by the smaller of the values $a + 3$ and $\hat{m}$, and so on. The process stops when a hypothesis is rejected; subsequently, all the succeeding ones are also rejected.

The reason this procedure is considered as an improvement of Hochberg's technique is that one never needs to multiply a p_i by a correction factor larger than the number of true H_{oi} s. The p_{ia} s can be defined in the following way: Each p_{ia} is the product that would test the corresponding H_{oi} , if hypothetically there would be no rejections until the smallest p_i . Whenever such product is determined to be larger than the one preceding it in the testing procedure, the corresponding p_{ia} is assumed to be equal to the previous one.

Brown and Russell^[5] studied both the FWER control and the power of 17 different P -value-based adjustment techniques (which includes nine step-down or step-up procedures and eight methods based on the parametric or nonparametric estimation of the distribution function of the P_i s). They simulated two different numbers of endpoints, three patterns of correlation among endpoints, three distributions of truth and falseness among the H_{oi} s, and two different amounts of deviation from the null hypotheses. Each statistical technique was applied 10,000 times in each of the 36 simulated situations, with $\alpha = 0.05$. The authors found that the improved Hochberg's procedure (see earlier discussion)^[10] falsely rejects any true H_{oi} at most 5.16% of the time. As for power, that method is consistently superior to seven other techniques in all experimental situations. No other examined procedure approaches this level of power achievement. Thus concluding their review, the authors recommended the improved Hochberg's step-up procedure over other P -value-based techniques.

Adjusted confidence intervals of outcome corresponding to step-down and step-up procedures are generally not easily available. Indeed, the estimated number of true null hypotheses is not immediately useful for confidence interval computation. Some particular results are worked out in Hayter and Hsu.^[12]

It is difficult to imagine the algorithm to compute the optimal sample size of a future trial to be analyzed by the step-up or step-down procedures. However, if one plans to use the improved Hochberg method, a reasonable guess could be made in the following way. From prior knowledge, one can obtain an estimate $\hat{m}$ of the number of true H_{oi} s in the future trial (it should be less than $k/2$; otherwise, the choice of the primary endpoints of the trial needs to be reconsidered). First, one must identify the endpoint on which the expected standardized effect of T , if present, is the smallest. Then one should determine the minimum clinically relevant effect of T on this endpoint (it should be less than the expected effect; otherwise, the endpoint should not have been chosen as a primary one). The next step would be to compute the required sample size to achieve the desired power (e.g., 0.8), as if the analysis were made on just this endpoint with a Type I error probability of $\alpha/\hat{m}$ (e.g., 0.05/ $\hat{m}$).

Techniques Based on the Distribution or the Correlation Structure of the Endpoint

A method based on the estimation of the correlation between endpoints is the one proposed by Tamhane.^[13] The adjusted p_i of each endpoint is computed by the following equation:

$$p_{ia} = 1 - (1 - p_i)^{k(1-\bar{p})} \quad (4)$$

where k is the number of endpoints and $\bar{p}$ is their average sample correlation (this can be computed from the sample correlation matrix of the endpoints, which is produced by any standard statistical program). The rationale behind the equation is largely commonsense: when the endpoints are completely independent, $\bar{p} = 0$, and Tamhane's formula turns out to be the simple correction Eq. (3) for independent tests. However, when all the correlations are 1—that is, all the endpoints are really just one endpoint (but for additive and multiplicative constants)—then the equation fittingly does not correct the raw p_i s at all. Eq. (4) has the advantage of simplicity, but it is not supported by any theoretical evidence.

Sankoh et al.^[6] empirically studied the performance of two similar correction equations, based on the estimation of the correlation between endpoints. Sankoh's simulations show that they are rather liberal. For both equations, the percentage of false significant results can be as high as 12% when the declared significance level of the procedure is 0.05. Sankoh proposes a method to correct their error rate, based on simulations (see later discussion).

Tamhane's formula can be used to construct confidence intervals for the endpoint differences adjusted for multiplicity. The per-interval confidence level, $1 - \alpha_c$, can be determined by the following equation:

$$(1 - \alpha_c)^{k(1-\bar{p})} = 1 - \alpha \quad (5)$$

If each confidence interval is computed at level $1 - \alpha_c$, then the probability of obtaining all intervals to include the true parameters should be $1 - \alpha$. However, this value of FWER could be optimistic, depending on the validity of Tamhane's formula. Empirical validation of the technique is needed.

From Tamhane's formula, one can compute the approximate sample size required for a multiple-endpoint clinical trial: one needs to know, or estimate from prior knowledge, the average correlation between endpoints. An example of sample size computation is as follows: Imagine a trial with eight endpoints, with a foreseen mean correlation of 0.7. Use Eq. (5) to compute the per-comparison significance level α_c required to achieve the desired global α . Compute α_c by solving the following equation:

$$1 - (1 - \alpha_c)^{8(1-0.7)} = 0.05$$

The solution is $\alpha_c = 0.027$. Then compute the sample size required for a level 0.027 test (with the desired power) applied to the endpoint with the smallest expected standardized treatment effect. This should also be the required sample size of the trial.

Tamhane^[13] also describes the *bootstrap* (or resampling) technique, which adjusts the p_i s by empirically estimating their distribution under H_0 . The rationale behind the bootstrap technique goes as follows: The probability distribution of any quantity Q meant to compare the groups of the trial can be estimated from its observed frequency distribution. If the null hypothesis is true for all endpoints, then the T and C samples of the trial differ in no systematic way; they come from the same population. So under H_0 , the two treatment groups can be thought of as random subsamples extracted from the total trial sample. One can artificially extract, with replacement, thousands more couples of random subsamples from the total trial sample; under H_0 , they all belong to the same population as the real data. In those artificial couples of subsamples, one can observe the empirical frequency distribution of the minimum P_i of the endpoints. So the frequency with which the minimum P_i is equal to or lower than a certain p_j obtained in the original data can be observed. It estimates the probability of obtaining such a p_j or a smaller P -value for at least one endpoint if H_0 is true. In other words, it is an estimate of p_{ia} . Pooling the samples does not change the correlation of the endpoints. Therefore the bootstrap adjustment estimates p_{ia} s based on exact correlations. However, unlike the P -value-based techniques, it fails to take into account the complete set of p_i s when adjusting each of them. In other words, the adjustment is made assuming that all H_{0i} s are true, which is probably conservative. Step-down and set-up versions of the procedure are available.^[14–16] The step-down version follows the logic of Holm's method: arrange the p_i s in increasing order. Resample data containing all endpoints to adjust the minimum p_i . Then exclude the corresponding endpoint from the data resampled to adjust the second smallest p_i . Third, also exclude the endpoint corresponding to the second p_i from the resampling, and adjust the third smallest endpoint. Go on until all the endpoints are adjusted. This method has been implemented in SAS, to correct the P -values of the t -test and the Fisher exact test for proportions, among others. It is invoked with the PROC MULTTEST command with the options BOOTSTRAP and STEPDOWN.^[17]

Techniques to Analyze Categorical and Ordinal Endpoints, Based on Discrete Probability Distributions

Some interesting methods based on the distribution of the observations are available to analyze dichotomous multiple endpoints; they are based on the "exact" Fisher test for the equality of two proportions. To use them, this test must be applied to compare the frequencies of *good* outcomes

of the two arms of the trial for each endpoint. It produces discrete P -values, with the consequence that p_i s lower than certain bounds are impossible. If, for a given endpoint i , one acquires a p_i smaller than the minimum possible P -value for every other endpoint, then no correction is needed for that p_i . Indeed, it can arise by chance only in one comparison: the one where it was obtained. Hence no multiple-testing bias exists. If only a subset of q comparisons can generate P -values equal to or smaller than p_i , then the Bonferroni correction should take into account only these q comparisons. Indeed, p_i or a smaller P -value can arise by chance only in these q comparisons but not in the whole set of k tests. Therefore one can accept $p_{ia} = qp_i$. To establish the minimum possible (one-sided) value of P_i for each comparison, the following equation is available:

$$\frac{\binom{g}{n_T}}{\binom{n}{n_T}} \text{ if } g \geq n_T \text{ and } \frac{\binom{n-g}{n_T-g}}{\binom{n}{n_T}} \text{ if } g < n_T \quad (6)$$

where n is the total number of subjects, n_T is the number treated, and g is the number of observations with the *good* outcome.

Following this logic, Mantel^[18] proposed a more precise multiple comparison procedure for the Fisher test. To adjust a p_i , one adds together the largest theoretically possible P -values of all other comparisons, which are equal to or smaller than p_i . Of course, in order to follow this procedure, one has to know all the possible values P_j of each comparison. They are obtained from the hypergeometric probability distribution of g_T : the number of subjects in the treated group experiencing the *good* outcome:

$$\mathcal{P}(g_T) = \frac{\binom{g}{g_T} \binom{n-g}{n_T-g_T}}{\binom{n}{n_T}} \quad (7)$$

Consider the following example. Imagine a trial with five dichotomous endpoints (say) A, B, C, D, E. The observed p_i of endpoint A is 0.019. To correct it, obtain the total number g of subjects with *good* outcome, observed for endpoint B. Compute all its possible P -values by substituting each possible value of g_T into Eq. (7). Do the same for endpoints C, D, and E. Now among all possible P -values computed for endpoints B, C, D, and E, look for those equal to or smaller than 0.019. Imagine that the largest of such values for endpoint B is 0.016 and that the largest for endpoint D is 0.012. Endpoints C and E have no possible P -values smaller than 0.019. Then the adjusted P -value of endpoint A is $0.019 + 0.016 + 0.012 = 0.047$.

This procedure can be used only when the theoretically possible values of P_i of the k comparisons are known. This takes place when small frequencies are analyzed via the Fisher exact test, but it also happens when small data

sets are analyzed by nonparametric techniques, e.g., the Wilcoxon test. Therefore Mantels' adjustment method can also be applied to ordinal data.

The discrete distribution of the endpoints can be exploited together with Hochberg's improved set-up procedure. One could proceed in the following way: Start Hochberg's improved procedure as usual, by putting the p_i s in decreasing order and by retaining all H_{0i} s corresponding to p_i 's $> \alpha$. From the second step onward, multiply the p_i under scrutiny by the minimum of these three numbers: $\hat{m}$ (the graphically estimated number of true H_{0i} s), $a_p + 1$ (the number of retained hypotheses in all preceding steps + 1), and q (the number of comparisons that can generate P -values equal to or smaller than p_i). If the obtained product is larger than α , then retain the corresponding hypothesis and examine the next p_i . Otherwise, reject the corresponding hypothesis and all the succeeding ones. This combined procedure should allow interesting power gains, because q tends to be small when a is large, and vice versa.

False Discovery Rate

An interesting alternative to the usual approach is the one proposed by Benjamini and Hochberg.^[19] They argue that it is sometimes more interesting to control the proportion of false rejections than to keep low the probability of at least one false-positive result. This seems to be a reasonable point of view when some tens of endpoints are to be tested and the researcher has no strong interest in any single one but rather looks for clusters of affected endpoints. The authors define the false-discovery rate as the expected proportion of rejected true H_{0i} s among all rejected H_{0i} s. They describe a test procedure and prove that (under stochastic independence of the endpoints unaffected by T) it warrants an expected false-discovery rate lower than a chosen value α_R (e.g., $\alpha_R = 0.05$). The procedure goes as follows: Arrange the raw p_i s in decreasing order. Compare the largest p_i with α_R : If it is smaller or equal to α_R , then reject all hypotheses. Otherwise, retain the corresponding hypothesis and compare the second largest p_i with $(k-1)\alpha_R/k$. If its value is smaller or equal, reject the corresponding H_{0i} and all the succeeding H_{0i} s. Otherwise, retain the corresponding hypothesis and compare the third largest p_i with $(k-2)\alpha_R/k$, etc. Continue in this manner until either a rejection ensues or the last p_i has been compared to α_R/k . Not surprisingly, the simulations show that, mostly when $k > 10$, this method applied within $\alpha_R = 0.05$ has a much higher power than the techniques that keep the FWER below 0.05.

INFERRING THE GLOBAL SUPERIORITY OF THE TREATMENT FROM THE COMBINED EVIDENCE OF ALL ENDPOINTS

Establishing the global superiority of T can be thought of as a single-hypothesis-testing problem. The multivariate

null hypothesis to be rejected H_0 declares that the true differences between the two arms are zero for *all* endpoints. Many alternative hypotheses are conceivable; it is important to choose the one that is relevant to prove in the trial at hand. The different multivariate alternative hypotheses that we consider are the following.

1. $\sim H_0$ is an alternative to H_0 , which contains and mixes up every possible difference of the effect of T and C . Inequalities of opposite sign for different endpoints are included in $\sim H_0$. It is the complement of H_0 .
2. $H_{T \geq C}$ is an alternative to H_0 , which states that T has a better effect than C on at least one endpoint and has no worse effect on any endpoint.
3. H_A is an alternative hypothesis to H_0 , which states that the average (defined somehow) of the effects of T on all endpoints is better than the average effect of C .

All these hypotheses state that the effects of T and C are different, but they do not identify the affected endpoints. Thus they are less informative than the alternative hypotheses concerning single endpoints. However, they are proved by just one test, whereas the $\sim H_0$ s are many and require many tests. For that reason, the procedures designed to prove $\sim H$, $H_{T \geq C}$, or H_A are often much more powerful than those used to test the H_0 s. They are to be considered especially in the final stage of the research on a treatment, when one is often more interested in assessing its multidimensional efficacy than in describing accurately the pattern of its clinical effects. For each of the three alternative hypotheses just mentioned, different statistical procedures are recommended.

To use the procedures described next correctly, be sure to measure all endpoints in such a way that positive differences always correspond to a more favorable outcome.

Techniques Powerful in Detecting $\sim H_0$

The alternative hypothesis $\sim H_0$ is rarely an interesting one; the discovery that some endpoints are favorably (and others unfavorably) affected by T , without identifying the concerned endpoints, can rarely have practical consequences. In any case, two procedures can be recommended to prove $\sim H_0$. Hotelling's T^2 is the uniformly most powerful test over $\sim H_0$ (subject to some invariance conditions) when the endpoints are multivariate Gaussian.^[20,21] This means that it detects violations of the null hypothesis, when the truth lies anywhere in the specified alternative hypothesis, with higher probability than every other test. This test is routinely performed by any program of multivariate analysis of variance (such as multiple analysis of variance, MANOVA, of SPSS or GLM of SAS). To apply it, one just has to compare the two arms by such programs, inputting all the endpoints as response variables.

If the endpoints are far from Gaussian, a “discriminant” logistic regression might work better, as suggested

by Cupples et al.^[22] The procedure, which can also be used with categorical endpoints, goes as follows: First, fit a logistic model with the allocated treatment as the *response* variable and no explanatory variables. Then fit another logistic model with the same response variable, with all the endpoints input as *explanatory* variables. The P -value of the multivariate comparison between treatments is equal to the P -value that compares the fit of the two logistic models. An example of a work that applies this technique can be found in Ref. [9]. However, note that, with this method, one cannot include prognostic covariates and stratification factors in the analysis.

Techniques Powerful in Detecting $H_{T \geq C}$

$H_{T \geq C}$ is certainly an interesting hypothesis to prove; however, the significance of the tests (powerful enough to detect it) is not necessarily a proof of it. Indeed, they can reject H_0 with a probability much larger than α , also when $H_{T \geq C}$ is far from true (this happens even if the Type I error rate is correctly kept to α). A typical situation where the tests described in this section reject H_0 when $H_{T \geq C}$ is false is when T has a strong favorable effect on some endpoints and a weaker unfavorable impact on others. Therefore to use the tests described in this paragraph as a proof of $H_{T \geq C}$, one must be sure that the difference of effect between T and C is zero or is favorable to T for all endpoints.

Schweder and Spjøtvoll^[11] proposed a *graphical technique*. This method is not a proper statistical test but allows one to estimate the number of endpoints that are favorably influenced by T . It is based on the raw one-sided p_i s computed on the single endpoints. (In case one-sided p_i s are not directly available, as happens with a χ^2 test, they can be computed in the following way: Observe in the data if the effect of T on the concerned endpoint appears to be favorable—e.g., the frequency of patients free of some discomfort appears to be increased by T .) If it appears as such, then: $p_{i \text{ one-sided}} = p_{i \text{ two-sided}}/2$; otherwise, $p_{i \text{ one-sided}} = 1 - (p_{i \text{ two-sided}}/2)$. The authors propose to plot the $(1 - p_i)$ s vs. their rank for all endpoints. If H_0 is true, then the plot should be a line through the origin with slope equal to $1/(k + 1)$. The reasons for this fact are as follows: From the definition of P -value, it derives that P_i is equal to or smaller than a determined value p_i , with probability equal to p_i . This means that P_i and $1 - P_i$ have a uniform probability distribution between 0 and 1. Now when k values are obtained from a random variable uniformly distributed in the interval 0–1, they are expected to divide the unit interval into $k + 1$ equal subintervals. Thus if one sequentially plots k points having as ordinates the $(1 - p_i)$ s in increasing order and as abscissas the k increasing numbers, which divide the 0–1 interval into $k + 1$ equal subintervals, then one expects to find each ordinate equal to the corresponding abscissa. Hence the interpolating curve is expected to be a line with slope 1. If one changes the scale of the x -axis and extends each subinterval to measure 1, the abscissas

become equal to the natural numbers from 1 to k . Then they are the ranks of the corresponding ordinates, i.e., of the $(1 - p_i)s$. Moreover, the former 0–1 interval extends to measure $k + 1$, so the slope of the line becomes $1/(k + 1)$ (because an increase of $k + 1$ on the x -axis corresponds to an increase of 1 on the y -axis).

If the number of true $H_{0i}s$ is $m < k$, the plot should deviate somewhere from a straight line. Indeed, some $(1 - p_i)s$ should be larger than expected, corresponding to the small p_i s of the false $H_{0i}s$. However, all of the leftmost points of the plot probably correspond to the large p_i s of the true null hypotheses. Hence they should plot a line. The expected slope of this line is $1/(m + 1)$. To understand such a development, remember that if two points of the plot correspond to true $H_{0i}s$, the expected difference of their ordinate is $1/(m + 1)$. Indeed, the $(1 - p_i)s$ that correspond to true $H_{0i}s$ are expected to generate $m + 1$ equal intervals between 0 and 1. Thus if one takes two points that correspond to true $H_{0i}s$ and whose abscissas differ by 1 (two consecutive points of the leftmost part of the plot), then they lie on a line with the expected slope $1/(m + 1)$. This fact gives a clue on how to estimate the number of true $H_{0i}s$: One can fit a straight line to the leftmost points of the plot that do not consistently deviate from a linear trend and compute its slope b . An estimate $\hat{m}$ of the number of the true $H_{0i}s$ is then yielded by $1/b - 1$. This estimate is slightly biased toward larger-than-true values.^[10]

Perlman^[23] found the likelihood ratio test for $H_{T \geq C}$ and derived its distribution for multivariate Gaussian endpoints with unknown covariance matrix. This test should have optimal properties; Lehmann^[21] writes that the likelihood ratio tests are often asymptotically most powerful in a uniform manner over the relevant alternative hypothesis, even in nonclassical situations. The power of Perlman's test has been empirically investigated by Follmann.^[24] He found that the test is actually preferable to both O'Brien's and Follmann's tests (see later discussion) only when some endpoints are truly favorably affected by T and a few number are unfavorably affected, a situation outside the range of $H_{T \geq C}$. Perlman's test is difficult to compute and has not yet found its way into most known statistical programs. The following are simpler tests for multivariate Gaussian endpoints.

O'Brien's test^[25] is particularly powerful if the true effects are equal on all endpoints.^[24] To use it, one has to compute a numerator and a denominator of a t -test statistic in the following way: From a computer program, obtain the k -dimensional vector $\bar{y}_T$ of the outcomes of the endpoints averaged on the T sample and the analog vector $\bar{y}_C$ computed as on the C sample. Get the estimated covariance matrix $\hat{V}$ of the endpoints as well. Then, to obtain the numerator, multiply the inverse of the estimated covariance matrix ($\hat{V}^{-1}$) by the vector of the mean differences of outcome: $\bar{y}_T - \bar{y}_C$, and sum up the elements of the resulting vector [formally, the numerator is $1' \hat{V}^{-1}(\bar{y}_T - \bar{y}_C)$,

where 1 is the vector of 1s]. The denominator is given by the usual correcting factor of t -tests: $\sqrt{1/n_T + 1/n_C}$ multiplied by the square root of the sum of the elements of $\hat{V}^{-1}$. [Formally, the denominator is $\sqrt{1/n_T + 1/n_C(1' \hat{V}^{-1} 1)}$]. For two endpoints, these computations can easily be performed by hand. If the endpoints are more than three, some matrix algebra program must be used. The obtained t is compared with the usual tables of critical values of t with $n_T + n_C - 2k$ degrees of freedom.

O'Brien's test can be one-sided or two-sided with the same modalities of a usual t -test. If the one-sided version turns out to be significant, the conclusion does not necessarily state that $H_{T \geq C}$ is true (although this is a very likely outcome). One has just proved that the expected value of the numerator of t , i.e., $1' \hat{V}^{-1} E(y_T - y_C)$ is positive. To see what this means, consider the case when the endpoints are independent. In that case, the numerator of O'Brien's test becomes the sum of the endpoint mean differences, each divided by the respective endpoint variance. So when the endpoints are independent, the hypothesis proved by the test states that the sum of the expected effects of T on all the endpoints, divided by their variances, is positive.

A very interesting feature of O'Brien's test is that, in its two-sided version, it can be applied to the comparison of more than two groups in stratified trials with prognostic covariates. (This can be carried out under the condition that the covariance matrix of the endpoints is the same within all strata, and conditional on all values of the prognostic covariates). To apply O'Brien's test in this general form, compute for each patient the quantity $u = 1' \hat{V}^{-1} y$ (where y is the vector of outcomes of the patient for all endpoints). Then, use u as the response variable in a usual program of analysis of variance.

Simulations show that this procedure keeps the FWER fairly under control, even when the data have exponential or Cauchy distributions.^[25] Follmann^[24] compared its power with that of Perlman's and his own test. He found that O'Brien's test is by far the most powerful version to detect $H_{T \geq C}$ when the endpoints are independent. Hence its use is recommended for nearly independent endpoints when one is certain that, if T is truly effective, it is so for all endpoints. O'Brien's test is also preferable with moderately positively correlated endpoints, if the true effects on all endpoints are very similar.

Tang et al.^[26] give a simplified approximate version of the likelihood ratio test of Perlman. The computation of Tang's test involves the Cholesky decomposition of the covariance matrix of the endpoints and other moderately complex matrix manipulations. The details are given in the original paper, together with the table of the critical values of the test statistic for up to 10 endpoints. If that table is not sufficient to analyze someone's data, the authors provide a simple formula (4.1 of their paper) for the computation of the P -value. It should not be excessively

difficult to implement that formula if the number of endpoints is not too high. The simulations performed by Tang and colleagues compare the power of their test to that of O'Brien's. They show that O'Brien's test is superior when the true effects of T on all endpoints are similar and that their test is superior in the opposite case.

Tang's test is intrinsically one-sided, but its conception is such that it can be significant in situations in which T is not superior to C . For instance, imagine that T and C are compared on uncorrelated endpoints. In this case, the test statistic is a weighted mean of the squared positive endpoint differences. If T has a strong favorable effect on one endpoint, but also an equally strong unfavorable one on the other endpoint, the test may be significant if we use it to demonstrate the superiority either of T or that of C . Therefore to apply Tang's one-sided test, it is not sufficient to adopt the pragmatic "approve or disapprove" point of view on a treatment evaluation, i.e., to merge countereffects and no effects in one null hypothesis (the logic that justifies one-sided tests in a single-endpoint trial). Indeed, overwhelming countereffects do not avoid Tang's tests stating significant favorable effects.

Follmann^[27] has proved that when Tang's method is applied to two positively correlated endpoints, it can become significant, even when the sample means of the two endpoints are both negatively affected by the treatment. This is not a crippling flaw of the test, however, because one could apply Tang's test at the condition that at least one of the endpoints is improved in the T sample. If this condition is not fulfilled, the null hypothesis could be accepted without further computations.

Follmann^[24] conceived a *one-sided modified T^2 test* for multivariate Gaussian endpoints, which joins ease of use, theoretically exact control of the α level, and good power to detect a large spectrum of alternative hypotheses within $H_{T \geq C}$. Its procedure with significance level α is as follows: Compute the mean difference between T and C of each endpoint, $\bar{y}_T - \bar{y}_C$, and sum them up over all endpoints. If the sum is negative, then retain H_0 . Otherwise, compare the two samples by a usual Hotelling's T^2 test: Reject H_0 if the test statistic is larger than the 2α critical value. In other words, the P -value of Follmann's test is *half* the P -value written on the output of the T^2 computation. Follmann proves that the Type I error rate of his test is always below α . With extensive simulations, he shows that his test is more powerful in detecting $H_{T \geq C}$ than the theoretically optimal Perlman's likelihood ratio test when the endpoints are moderately positively correlated ($\rho = 0.75$). In this situation, if the true effect of T , although favorable everywhere, is rather heterogeneous among the endpoints, Follmann's test is also superior to O'Brien's and should be recommended.

Rom^[28] proposes a global one-sided test for multiple dichotomous endpoints based on their joint distribution. The author gives an example of an application of his procedure

to the case of two endpoints with hypergeometric distribution. However, for three or more endpoints, Rom's method probably needs the application of bootstrap techniques to estimate the joint probability distribution of the endpoints.

Techniques Powerful in Detecting H_A

When one expects T to be superior to C on average but also to have some countereffects, the tests described in this section become relevant. Of course, according to the meaning given to the term *average superiority*, the chosen test will be different.

Follmann^[24] quotes the likelihood ratio test for a H_A , defined as follows: $E(y_T - y_C) > 0$ (i.e., the arithmetic mean of the effect of T on all endpoints is positive). However, he writes that this test is not yet available if the covariance matrix of the endpoints is unknown.

Follmann^[27] proposes a very simple and appealing test for multivariate normal endpoints. A slight generalization of his method is as follows: For each subject, multiply each endpoint measure by a predetermined fixed weight, and sum all the products to obtain a unique score. Then perform a usual analysis of variance on this score. This procedure is correct because, if the endpoints are Gaussian, every linear combination of these endpoints is likewise Gaussian. The test has a one-sided version, easily obtained from the two-sided one, by considering the observed score mean difference between T and C . If this difference is favorable to T , then $P_{\text{one-sided}} = P_{\text{two-sided}}/2$; otherwise, $P_{\text{one-sided}} = 1 - (P_{\text{two-sided}}/2)$. The alternative hypothesis proved by this test, if it is significant, is that the predetermined linear combination of the endpoint outcomes has a more favorable expected value for T than for C .

Follmann affirms that his method may be used when the multiple endpoints are surrogate of one "hard" endpoint difficult to measure directly. The linear combination of endpoint outcomes should be a linear model previously fitted to independent data, which turned out to be reasonably predictive of the "hard" endpoint. However, his method should also be considered when the "hard" endpoint aimed at is *impossible* to measure directly, e.g., cognitive impairment or quality of life. In this type of situation, the weights given to each endpoint should be attributed by experts of the field. The subjective choice of the weights should not be a problem if they are clearly stated in the protocol of the analysis.

In Follmann's simulations of a two-endpoint trial, the power of his test is always superior to the mean power of the univariate tests applied to the single endpoints when both endpoints are truly favorably affected by the treatment. Moreover, Follmann finds that the form of the rejection region of his test makes sense from a substantive point of view. Indeed, whatever is the number and the correlation structure of the endpoints, all the observed outcomes leading to the rejection of the null hypothesis correspond

to a better outcome score than all the outcomes leading to retain H_0 .

If applied to an independently measurable “hard” endpoint, such as mortality, Follmann’s procedure allows one to compute confidence intervals for it. Moreover, his score can be used as the response variable of a general linear model, allowing all the trial design features—more than two arms, stratification, random factors, prognostic covariates, repeated measures, etc.—to be taken into account in the statistical analysis.

From Follmann’s method, a formula can be deduced for the computation of the required sample size of a trial. Proceed as follows: Ask the field experts the minimum clinically relevant effect difference of each endpoint, assuming other endpoints stay unaffected. Then compute the weighted mean of the minimum clinically relevant differences, using the same weights chosen for the analysis. This mean should be a meaningful minimum clinically relevant score difference. Compute the variance of the score from the variances of the endpoints and their correlation (for the computation formula, see Ref. [29]). After knowing the minimum clinically relevant difference and the variance of the score, obtain the required sample size from the usual tables published for univariate trials.

O’Brien^[25] proposed a rank-based test: the measures of each endpoint are ranked among all subjects. (A better outcome has higher rank than a worse one.) Then, for each subject, the sum of the ranks of all endpoint outcomes is computed. This sum is asymptotically Gaussian and can be used as response variable of a general linear model. The test can be one- or two-sided. The alternative hypothesis proved by the one-sided version is as follows: “The probability that a subject of the T population has a better outcome on any endpoint than a subject of the C population is on average larger than 0.5.” O’Brien’s simulations show that the rank-sum test has a reasonable control of the Type I error rate; it rejects the true null hypothesis a maximum of 6.3% of the times for a declared $\alpha = 0.05$ in the set of situations considered by the author. The power of the rank-sum test is inferior to the power of the parametric test proposed by same author (see earlier discussion) in situations where the last should perform at its best, i.e., when the endpoints are multivariate Gaussian and all are truly improved by similar amounts by T . When the endpoints are not Gaussian, the rank-sum test turns out to be superior. Hence the rank-sum test is recommended when the endpoints are certainly far from the Gaussian distribution.

In the particular case where only one endpoint is actually affected by T , Follmann^[27] empirically proved that the Bonferroni correction is optimal. However, this situation should not arise if the endpoints of the trial are well chosen. If the Bonferroni correction, or other techniques devised to test the single H_{0i} s, are used to test the global H_0 , the multivariate P is equal to the smallest of the p ias computed for the H_{0i} s.

REGULATORY AGENCIES AND THE MULTIPLE-ENDPOINT ISSUE

Regulatory agencies do not give very detailed guidelines for the analysis of multiple endpoints in clinical trials. They require a fair control of the Type I error rate without giving any indication of a preferred technique. For instance, in the guidance for rheumatoid arthritis treatment evaluation,^[30] the FDA considers the following alternatives. 1) Three out of the four primary endpoints relevant to the pathology are significantly improved by T . 2) A multivariate statistical method is applied. 3) The efficacy variables are combined within patients (composite endpoint), and the weights used are clearly defined in the study protocol.

An example of the concern of the statisticians in the regulatory agencies for the analysis of multiple-endpoint clinical trials is expressed, for instance, by Sankoh et al.^[6] They give a fair and clear account of various adjustment procedures. The authors also propose a simulation-based method to correct the FWER of some P -value-based and ad hoc techniques. Their method is as follows: Estimate the sample correlation matrix among endpoints without breaking the blind code of the trial. Simulate thousands of trials with the same correlation structure and no effect of T . Apply the adjustment defined in the protocol to each virtual trial sample, and count the frequency of rejections. If the proportion of rejections is larger than the chosen rate (e.g., 0.05), apply the same adjustment again but using a smaller nominal α level (e.g., 0.04) in the formulae. Continue trying different nominal values of α until the proportion of rejections is pared down to the desired value (in our example, 0.05). Use the so-identified nominal α , instead of 0.05, in the adjustment procedures for the analysis of the real trial.

The authors also discuss the use of global test procedures and underscore the necessity that a global alternative hypothesis should be meaningful. As Sankoh points out, global tests are certainly not appropriate when each endpoint has a completely different pathologic meaning.

Multiple-Dose Bioequivalence Studies

Vernon M. Chinchili

Penn State College of Medicine, Hershey, Pennsylvania, U.S.A.

Abstract

The purpose of a bioequivalence study is to determine if two products are sufficiently similar in their rate and extent of drug absorption so that they can be interchangeably used in a patient to produce the same therapeutic outcome. The focus of this entry is the statistical assessment of average bioequivalence in multiple-dose studies.

INTRODUCTION

The purpose of a bioequivalence study is to determine if two products, containing the same amount of therapeutic agent, are sufficiently similar in their rate and extent of drug absorption so that they can be interchangeably used in a patient to produce the same therapeutic outcome.

Methods currently required by the Food and Drug Administration (FDA) generally involve a single measurement of the metrics of rate and extent of absorption [area under the curve (AUC), $C_{\max}$, $T_{\max}$] in 16–32 normal, healthy volunteers. This procedure is referred to as “average bioequivalence” because only the means of the two products are statistically compared. There are several assumptions inherent in this method:

1. The sample of individuals is homogeneous.
2. The volunteer study population is representative of the target patient populations.
3. For each metric, the variances of the test and reference products are the same.

OVERVIEW

The modification of average bioequivalence is population bioequivalence, in which estimated means and variances are compared. Generally, it is recognized that population bioequivalence is adequate to show that the test product is safe and effective in the population and is therefore prescribable. However, this process does not examine differences between the test and reference products in individual subjects (or patients). Therefore it may not be a good indicator of whether the test and reference products can be interchangeably used in individual subjects. This has been referred to as the “switchability” of products.^[1] Anderson and Hauck^[2] proposed an early approach for assessing the switchability, or individual bioequivalence, of test and reference products.

To better assess the interchangeability or switchability of products in individual subjects, there has been increasing scientific interest in developing new statistical procedures that allow the assessment of the following questions, which are not adequately examined by current methods of population bioequivalence.^[1,3,4] Although regulatory interest in this issue was intense during the 1990s,^[5] recent regulatory guidelines have shelved the pursuit of requiring individual bioequivalence.^[6]

However, scientific interest remains for addressing some of the following questions:

1. Do the intrasubject variances of the test and reference products differ?
2. Are there subsets of the study population (and thus, possibly, the patient population) that show greater differences between test and reference products?
3. Can these differences be statistically detected as a subject $\times$ treatment interaction?

These questions can be answered only if replicate measures in the same individual are available. There are basically two experimental approaches to obtaining replicate measures: replicate designs in single-dose studies and repeated-measurements designs in multiple-dose studies.

A replicate design in a single-dose study refers to the situation in which a subject receives each of the test and reference products in a single-dose administration, and in which each event is replicated on more than one occasion. Thus a replicate design in a single-dose study provides replicate observations of the important metrics.

For subjects in a multiple-dose study, each formulation is administered on repeated regular intervals in order to attain steady state conditions. Blood sampling is performed after the steady state conditions have supposedly occurred. However, multiple-dose studies provide the opportunity to conduct blood sampling on repeated occasions for each subject within each period of the crossover design. For example, if subjects in a multiple-dose study

are to be administered a formulation on each of d consecutive days, and it takes $d-q+1$ days to attain steady state conditions, then this multiple-dose study can provide multiple observations of the important metrics on q days of that period (days $d-q+1$ through d).

The focus of the following statistical section is the assessment of average bioequivalence, although multiple-dose studies provide an appropriate framework for the assessment of individual bioequivalence. Wang et al.^[7] describe an approach for estimating AUC in a multiple-dose study in which there is noncompliance. However, the following section assumes full compliance.

STATISTICAL METHODS

We consider a general $s \times p$ crossover design in which subjects are randomized to s sequences containing test (T) and reference (R) formulations administered over p periods. Within sequence i , $i = 1, \dots, s$, the test formulation appears in p_{Ti} periods and the reference formulation appears in p_{Ri} periods, with $p_{Ti} + p_{Ri} = p$. Suppose that measurements are taken on q occasions within each period after steady state conditions have been attained. Let

$$\begin{aligned} \mathbf{Y}_{Tijk} &= [\mathbf{Y}_{Tijk1} \dots \mathbf{Y}_{Tijkq}]' \\ \mathbf{Y}_{Rijl} &= [\mathbf{Y}_{Rijl1} \dots \mathbf{Y}_{Rijlq}]' \end{aligned} \quad (1)$$

denote the q vector of observations for the k th occurrence of the test formulation and the l th occurrence of the reference formulation, respectively, for the j th subject within the i th sequence, $i = 1, \dots, s$, $j = 1, \dots, n_i$, $k = 1, \dots, p_{Ti}$, and $l = 1, \dots, p_{Ri}$. For example, the $\mathbf{Y}_{Tijk}$ and $\mathbf{Y}_{Rijl}$ could denote measurements of AUC or $C_{\max}$ on the natural log scale. We use the natural log transformation because there is reason to believe that AUC and $C_{\max}$ are usually log-normally distributed.^[8]

The model we assume is

$$\mathbf{Y}_{Tijk} = \mu_T + \mu_{Tm}^* + U_{Tij} + \gamma_{Tikm} + E_{Tijk} \quad (2a)$$

$$\mathbf{Y}_{Rijl} = \mu_R + \mu_{Rm}^* + U_{Rij} + \gamma_{Rilm} + E_{Rijl} \quad (2b)$$

for $i = 1, \dots, s$, $j = 1, \dots, n_i$, $k = 1, \dots, p_{Ti}$, $l = 1, \dots, p_{Ri}$, and $m = 1, \dots, q$, where

μ_T = population mean for formulation T

μ_R = population mean for formulation R

μ_{Tm}^* = deviation from population mean at occurrence m for formulation T

μ_{Rm}^* = deviation from population mean at occurrence m for formulation R

γ_{Tikm} = nuisance parameter (occurrence $\times$ sequence nested within formulation T)

γ_{Rilm} = nuisance parameter (occurrence $\times$ sequence nested within formulation R)

$\mathbf{U}_{ij} = [U_{Tij} \ U_{Rij}]'$ = bivariate random subject effect

$\mathbf{E}_{Tijk} = [E_{Tijk1} \dots E_{Tijkq}]'$ = q vector of random errors under formulation T

$\mathbf{E}_{Rijl} = [E_{Rijl1} \dots E_{Rijlq}]'$ = q vector of random errors under formulation R

Constraints on the nuisance parameters are necessary to prevent overparameterization of the model with respect to the fixed location parameters:

$$\sum_{m=1}^q \mu_{Tm}^* = 0 \quad \text{and} \quad \sum_{m=1}^q \mu_{Rm}^* = 0 \quad (3a)$$

$$\sum_{i=1}^s \sum_{k=1}^{p_{Ti}} \gamma_{Tikm} = 0 \quad \text{and} \quad (3b)$$

$$\sum_{i=1}^s \sum_{l=1}^{p_{Ri}} \gamma_{Rilm} = 0$$

for each $m = 1, \dots, q$.

With the constraints in place, the model in Eqs. 2 and 3 is said to be saturated because there are a total of spq unrestricted location parameters that corresponds exactly to the number of cells in the $s \times p$ crossover design with q occurrences within each of the p periods. It is not necessary to include all the nuisance parameters in the model and force it to be saturated. Although a saturated model is conservative, it protects against confounding of the formulation means with any excluded nuisance parameters.

The nuisance parameters $\mu_T^* = [\mu_{T1}^* \ \mu_{T2}^* \dots \mu_{Tq}^*]'$ and $\mu_R^* = [\mu_{R1}^* \ \mu_{R2}^* \dots \mu_{Rq}^*]'$ are of special interest because they represent deviations from test and reference formulation means, respectively, over the q occurrences within each period. If steady-state conditions have not been achieved, then it is anticipated that the estimates of μ_T^* and μ_R^* will significantly differ from zero and the variability of the estimated μ_T and μ_R will be relatively large. In such a situation, there will be decreased statistical power for bioequivalence testing.

In addition, we assume that carryover effects do not exist in the proposed model. This is a reasonable assumption in bioequivalence trials^[8] if the washout period is of adequate length; however, it may not be so for other types of crossover trials. If the existence of carryover effects is suspected, then the model can be modified to include them.

The distributional assumptions for the j th subject within the i th sequence, $i = 1, \dots, s$, and $j = 1, \dots, n_i$, are as follows:

$$\mathbf{U}_{ij} = \begin{bmatrix} U_{Tij} \\ U_{Rij} \end{bmatrix} \sim N_2 \left(\begin{bmatrix} 0 \\ 0 \end{bmatrix}, \Omega = \begin{bmatrix} \omega_{TT} & \omega_{TR} \\ \omega_{TR} & \omega_{RR} \end{bmatrix} \right) \quad (4)$$

where Ω is an unknown positive definite matrix;

$$\mathbf{E}_{Tijk} \sim N_m(\mathbf{0}, \sigma_{Tm}^2 \mathbf{I}_m) \quad \text{and} \quad \mathbf{E}_{Rijl} \sim N_m(\mathbf{0}, \sigma_{Rm}^2 \mathbf{I}_m) \quad (7)$$

where σ_T^2 and σ_R^2 are unknown positive scalars and $\mathbf{I}_m$ is the $m \times m$ identity matrix. Further, we assume that the random subject effects and the random errors are mutually independent.

The model and assumptions described in Eqs. 1–7 are a generalization of those presented by Chinchilli et al.^[9] for multiple-dose studies with a 2×2 crossover design, and those given by Chinchilli and Esinhart^[10] for single-dose studies with an $s \times p$ crossover design. Other researchers, such as Ekbohm and Melander^[11] and Sheiner,^[1] have considered similar types of models with the distributional assumptions as Eqs. 6 and 7 for the case $q = 1$. The distributional assumptions in Eqs. 6 and 7 differ from those typically assumed for a crossover experiment, such as univariate random effects, i.e., $U_{Tij} = U_{Rij}$ for $i = 1, 2$ and $j = 1, \dots, n_j$, and homogeneous intrasubject variances, i.e., $\sigma_T^2 = \sigma_R^2$, such as the books by Jones and Kenward^[12] and Ratkowsky et al.^[13]

The model and assumptions in Eqs. 1–7 fall into the general realm of a mixed-effects linear model. Therefore standard statistical software packages can be invoked to perform a likelihood analysis of a particular data set. A special case of interest is a design that is uniform within sequences, defined by Laska et al.^[14] as a situation in which the test formulation appears the same number of times within each sequence ($p_{T1} = \dots = p_{Ts}$) and the reference formulation appears the same number of times within each sequence ($p_{R1} = \dots = p_{Rs}$). If the crossover design is uniform within sequences and the model is saturated in terms of the location parameters, then, as Chinchilli and Esinhart^[10] showed, the maximum likelihood (ML) and restricted maximum likelihood (REML) estimates of the location parameters and the variance–covariance components have a closed-form solution. Under these circumstances, if $\delta = \mu_T - \mu_R$, then

$$\hat{\delta} = \bar{Y}_{T\dots} - \bar{Y}_{R\dots} \quad (6)$$

is the ML and REML estimator of the formulation difference. The estimator in Eq. 8 is intuitive because it simply involves averaging the response over all appropriate observations. The variance expression for the estimator in Eq. 6 is

$$\text{var}(\hat{\delta}) = \left(\frac{1}{n_1} + \dots + \frac{1}{n_s} \right) \times \left(\omega_{TT} + \omega_{RR} - 2\omega_{TR} + \frac{1}{p_T q} \sigma_T^2 + \frac{1}{p_R q} \sigma_R^2 \right) / s^2 \quad (7)$$

The variance formula in Eq. 7 is useful for sample-size calculations, as described in Ref. [9] for the 2×2 crossover design.

The typical approach for assessing bioequivalence with respect to average bioavailability based on pharmacokinetic endpoints such as AUC and $C_{\max}$ is the two 1-sided testing approach introduced by Schuirmann^[15] and the

corresponding $100(1 - \alpha)\%$ confidence interval for $\mu_T - \mu_R$ described by Berger and Hsu,^[16] denoted as $[\hat{\delta}_\alpha, \hat{\delta}_{1-\alpha}]$. For the confidence-interval approach, the endpoints of the confidence interval are exponentiated. It is then determined whether this exponentiated confidence interval lies within (0.80, 1.25). The null hypothesis of bioinequivalence at the α significance level is rejected in favor of the exponentiated $100(1 - \alpha)\%$ confidence interval that lies entirely within (0.80, 1.25).

RESULTS AND DISCUSSION

A multiple-dose study was conducted by the Department of Pharmacy and Pharmaceutics at Virginia Commonwealth University, supported by Mova Pharmaceutical Company, in order to assess the average bioequivalence of test and reference formulations of levethyroxine sodium. Their study consisted of 24 healthy male volunteers who were randomized to receive either sequence TR or sequence RT. Blood samples were drawn from each subject on days 41 and 43 of steady state within each period of formulation administration; so $q = 2$ in the notation of our model in Eqs. 2a, and 2b. For purposes of illustration, we focus on the analysis of AUC only.

We applied the natural log transformation to the data and proceeded with the statistical model and analysis as described earlier. The SAS code for the analysis using PROC MIXED is as follows:

```
PROC MIXED;
CLASS subject formulat;
MODEL log_auc = mu_t mu_r mustar_t mustar_r
gamma_t1 gamma_t2 gamma_r1 gamma_r2/NOINT
SOLUTION;
RANDOM mu_t mu_r/SUBJECT = subject TYPE =
UNG;
REPEATED/SUBJECT = subject TYPE = SIM R
GROUP = formulat;
ESTIMATE 'formulation diff' mu_t 1 mu_r -1 /DF = 22;
```

The uppercase components of the SAS code represent statements and keywords, whereas the lowercase components represent user-provided variable names and options. Variables corresponding to the two formulation means and the six nuisance parameters (mustar_t, mustar_r, gamma_t1, gamma_t2, gamma_r2, gamma_r2) are created using IF–THEN statements within an SAS DATA step. The RANDOM and REPEATED statements are constructed in a manner to provide the intersubject and intrasubject variance components, as described in the model and assumptions of the previous section. The ESTIMATE statement yields the estimated formulation difference and its standard error, which are needed to construct the 95% confidence interval for assessing average bioequivalence.

The estimated test and reference formulation means for the logarithm of the AUC are 6.892 and 6.886, respectively. None of the six estimated nuisance efforts are significantly different from zero ($p > 0.15$). The estimated variance components are as follows:

Parameter	Estimate
ω_{TT}	0.0518
ω_{RR}	0.0422
ω_{TR}	0.0400
σ_T^2	0.0035
σ_R^2	0.0039

With respect to the assessment of average bioequivalence, the ratio of the geometric means on the original scale is 1.001, and the 95% confidence interval using the Berger and Hsu^[16] approach is (0.96, 1.05). Therefore average bioequivalence is concluded for AUC. As an aside, the intrasubject variances of the two formulations, 0.0035 and 0.0039, appear to be very similar.

CONCLUSION

A bioequivalence study is used to determine if the rate and extent of drug absorption for a test product is similar to that of a reference product. A multiple-dose bioequivalence study provides the opportunity for more data on the rate and extent metrics, hence, it should yield more statistical power than a single-dose bioequivalence study. This paper describes a mixed-effects linear model for analyzing the data from a multiple-dose bioequivalence study and illustrates the analysis with a real-life example.

Multiple-Stage Designs: Phase II Cancer Trials

Masha Kocherginsky and Shang P. Lin

Department of Health Studies, The University of Chicago, Chicago, Illinois, U.S.A.

Abstract

This entry provides a review of several widely used multi-stage designs, along with some recently proposed modifications, improvements, and extensions. Binomial and trinomial response models are considered in detail, and some additional multi-stage designs are discussed.

Keywords: Cancer trials; Clinical trials; Group sequential methods; Multi-stage design.

INTRODUCTION

The primary objective of a Phase II cancer trial is to determine if a treatment is “active” or efficacious enough to warrant a definitive Phase III clinical trial. Traditionally, the development of Phase II trial designs has focused on cytotoxic chemotherapeutic agents, which are presumed to have clinical benefit by shrinking tumors. Typically, treatment in Phase II trials is administered to patients with metastatic disease who will be considered responsive or not based on tumor shrinkage. Past experience suggests that efficacy of a drug is disease-site specific; therefore, a Phase II trial is limited to a specific type of cancer. The kind of cancer against which the treatment is to be tested is determined through pre-clinical animal studies and Phase I clinical trials.

Tumor shrinkage remains the most common primary endpoint in Phase II cancer trials of cytotoxic agents. Tumor response can be determined in the first few months of treatment and usually has good correlation with survival. In order to obtain an objective evaluation of the response, the patients should have a disease whose severity in terms of tumor size can be measured through diagnostic tools, most commonly radiographic imaging such as CT or MRI.

Usually, a Phase II cancer trial is based on a one-sample statistic with binary response (treatment success or failure). The classical design is a single-stage procedure in which a fixed number of patients are accrued to receive the treatment. Based on the number of responses (i.e., successes) observed, one would decide whether the treatment holds sufficient promise to warrant further testing, typically in a Phase III trial. In this process, false-positive and false-negative errors (α and β) should be kept within pre-specified limits. The key design issue in this situation is determining the minimum sample size required and the number of responses needed to declare that the treatment is active.

Ethically the design should allow for early termination so that the number of patients exposed to treatment with poor activity is minimized (this is commonly referred to as “stopping for futility”). In this regard, a full sequential design in which analysis is performed after the outcome of each new patient becomes available is most efficient, but is difficult to implement. Multi-stage design is a compromise between the simplicity of single-stage design and the efficiency of full sequential design. Such design reduces, on the average, the number of patients required while keeping the trial logistics manageable.

Since Gehan^[1] proposed the use of a two-stage design in Phase II studies, a number of multi-stage designs, mostly for two stages, have been proposed in the literature. In general, they differ mainly in the number of stages, stopping rule, and optimality criterion. Some are not based on any optimization such as the Fleming’s^[2] designs, which focus on the spending of error rates at each stage. In terms of statistical properties and practical considerations, Mariani and Marubini^[3] have reviewed a number of multi-stage designs for Phase II cancer trials. Kramar et al.^[4] have described and compared designs of Gehan,^[1] Fleming,^[2] Simon,^[5] and Ensign et al.^[6] and Mariani and Marubini,^[7] and Perrone et al.^[8] have studied usage of the available statistical designs for Phase II cancer trials. Estimation of the binomial proportion at the end of a multi-stage trial is addressed by Jung et al.^[9] and Tsai et al.^[10] Jung et al.^[11] and Koyama and Chen^[12] discuss p-value calculation at the end of the trial. Advantages and disadvantages of randomized Phase II trials including a prospective control have been discussed (for example, Ref. [13]). Some new randomized multi-stage trial designs have been proposed by Jung^[14] for binomial outcome, and by Sun et al.^[15] for trinomial outcome, and the use of randomized discontinuation design has been proposed by Rosner et al.^[16] Seamless Phase II/III designs, which can also be considered multi-stage designs, have been reviewed by Thall.^[17]

Recent discoveries in molecular biology of cancer have led to the development of novel molecular targeted anti-cancer agents which target specific proteins involved in tumor growth, angiogenesis, metastases, and other cell processes. The effect of many such therapies is thought to be cytostatic, meaning that the drug slows down or stops tumor growth rather than shrinks existing tumors. The implicit assumption for such drugs is that tumor growth inhibition will translate into clinical benefit of increased progression-free or overall survival. Clearly, for such therapies the traditional dichotomous response-based endpoint is no longer appropriate because response rate is expected to be low. The need for alternative approaches to clinical trial design and endpoint selection for such agents has been well established.^[18] Some of the proposed endpoints include multinomial response categories, continuous endpoints (e.g., changes in tumor size), and time to progression or progression-free survival at a fixed time point.^[19,20] The use of randomized trials with a prospective control group to compensate for the lack of reliable historical control data for many cytostatic agents has also been discussed.^[13,21]

This paper provides a review of several widely used multi-stage designs, along with some recently proposed modifications, improvements, and extensions. Binomial and trinomial response models are considered in detail, and some additional multi-stage designs are discussed. We present the frequentist approach, while the reader is referred to Tan and Machin^[22] and references therein for discussion of the Bayesian approach. The rest of the chapter is as follows: the section “Hypothesis Testing” describes the hypothesis to be tested; “Single-Stage Design” discusses designs based on fixed-sample procedure, which serves to lay the foundation for the discussions of multi-stage designs given in section “Multi-stage Design,” and finally, some concluding remarks are given in “Conclusion.”

HYPOTHESIS TESTING

Because we would like to make a decision whether the treatment is active enough to warrant a Phase III trial, we consider the design within the hypothesis testing framework in which a null hypothesis (H_0) is compared to an alternative hypothesis (H_1). $H_0(H_1)$ states that the true response rate is not better (worse) than a pre-specified undesirable (desirable) level. A decision rule for acceptance or rejection of H_0 is then defined based on the number of responses. The design must take into account two possible errors that occur in the determination of activity or the response rate, namely, the probability of claiming that the treatment is active (or response rate is high) when it is inactive, and the probability of claiming the treatment is inactive (or tumor response rate is low) when it is active. Statisticians refer to these two errors as the type I error (false-positive error) and type II error (false-negative error)

respectively, and seek to control them at prescribed low levels α and β .

Binomial Response

Standard medical practice classifies the tumor response into four categories: (i) complete response (CR); (ii) partial response (PR); (iii) stable disease (SD); and (iv) progression of disease (PD) according to the Response Evaluation Criteria in Solid Tumors (RECIST).^[23] Often this initial classification is further grouped into two categories yielding a binomial response. For example, for solid tumors, response includes both complete and partial responses (50% or more reduction in tumor size), and non-response includes both stable disease and progression of disease.

When the efficacy of a treatment is defined as a binary endpoint (response/no response), the typical hypothesis we wish to test is

$$H_0 : p \leq p_0 \quad \text{versus} \quad H_1 : p \geq p_1 \quad (1)$$

where p is the true probability of response, p_0 is a selected undesirable response rate, and $p_1(>p_0)$ is a selected desirable response rate. The value of p_0 is selected as the response rate above which the treatment is considered as sufficiently active. The alternative value p_1 is selected as the value of the active response rate that needs to be detected with high probability (power). Note that rejection of H_0 only leads to the conclusion that $p > p_0$ and not that $p \geq p_1$. Hypothesis (1) remains the same when the role of “response” is exchanged with that of “no toxicity;” hence designs developed for the binomial response rate are also applicable for toxicity monitoring.

Trinomial Response

A CR, defined as complete disappearance of the tumor, is more desirable than a PR since a CR is more likely to signal an important anti-tumor effect and result in a survival improvement. To differentiate between CR and PR, one could consider a trinomial response model where a patient’s response has three possible outcomes: CR, PR, or NR (no response) with probabilities p_c , p_p and $(1-p_c-p_p)$ respectively. Panageas et al.^[24] have considered the following hypothesis testing:

$$\begin{aligned} H_0 : p_c \leq p_{0c} \text{ and } p_p \leq p_{0p} \quad & \text{versus} \\ H_1 : p_c \geq p_{1c} \text{ or } p_p \geq p_{1p} \end{aligned} \quad (2)$$

where p_{0c} and p_{0p} are selected undesirable CR rate and PR rate respectively, and $p_{1c}(>p_{0c})$ and $p_{1p}(>p_{0p})$ are selected desirable CR rate and PR rate respectively. If a more restrictive alternative hypothesis $H_1 : p_c \geq p_{1c}$ and $p_p \geq p_{1p}$ is considered, then hypothesis (2) reduces to hypothesis (1) when the CR and PR rates are combined. The combination

of complete and partial response rates (CR + PR) is often referred to as the objective response rate (OR).

Zee et al.^[25] and Freidlin et al.^[26] considered a different trinomial response model where a patient's response takes three possible outcomes: R(CR or PR), P(early progression), and S(stable disease) with probabilities p_r , p_p , and $(1 - p_r - p_p)$ respectively. This model differentiates between patients with stable disease and early progressive disease, rather than combining them as a non-response group. The hypothesis to be tested is:

$$\begin{aligned} H_0 : p_r \leq p_{0r} \text{ and } p_p \geq p_{0p} & \text{ versus} \\ H_1 : p_r \geq p_{1r} \text{ or } p_p \leq p_{1p} \end{aligned} \quad (3)$$

where p_{0r} and p_{1r} are the undesirable and desirable response rates, and p_{0p} and p_{1p} are the undesirable and desirable progression rates. Note that for the response rate the higher rate is more desirable, while for the progression rate the lower rate is more desirable. Thus in the above hypothesis we assume $p_{1r} > p_{0r}$ and $p_{1p} < p_{0p}$.

The hypothesis formulation in Zee et al. is particularly relevant to clinical trials of cytostatic agents because the alternative hypothesis of either improved response or decreased early progression represents the clinical perspective. However, Freidlin et al.^[26] note that from the design point of view, the more restricted alternative hypothesis $H_1 : p_r \geq p_{1r}$ and $p_p \leq p_{1p}$ is more appropriate because for some points in the alternative space (e.g., $p_r = 0$ and $p_p = p_{1p}$) defined with an "or" the hypothesis test will not have the stated false-negative error rate, i.e., will have low power.

Pragmatically, testing hypothesis (3) is equivalent to testing the hypothesis

$$\begin{aligned} H_0 : p_r \leq p_{0r} \text{ and } p_s \leq p_{0s} & \text{ versus} \\ H_1 : p_r \geq p_{1r} \text{ or } p_s \geq p_{1s} \end{aligned} \quad (3a)$$

where $p_s \equiv (1 - p_r - p_p)$ denotes the probability of S (stable disease), and p_{0s} and p_{1s} ($> p_{0s}$) are the undesirable and desirable stable disease rates. However, because disease progression is more critical than stable disease, hypothesis (3) specified in terms of progressive disease rate may be more directly relevant for making the decision of whether to accept or reject a new treatment. Furthermore, note that hypothesis (3a) is essentially the same as hypothesis (2) with the roles of R, S, and P are exchanged with CR, PR, and NR respectively.

SINGLE-STAGE DESIGN

The single-stage procedure is the classical approach to design a Phase II cancer trial. The analysis is performed after the planned number of patients has been accrued. Although its simplicity is desirable, for ethical reasons it is usually considered unacceptable for Phase II cancer

trials since it does not allow early termination of the trial when the treatment does not appear to be active (stopping for futility). Discussion of the single-stage design here serves to provide a foundation for multi-stage designs, and to highlight basic differences between single-stage and multi-stage designs.

Binomial Response

Let X be a random variable representing the number of responses in n patients. We denote the mass and cumulative binomial probability functions at $X = r$ as $b(r; p, n)$ and $B(r; p, n)$; respectively. Thus, $b(r; p, n) = \frac{n!}{r!(n-r)!} p^r (1-p)^{n-r}$ and $B(r; p, n) = \sum_{j=0}^r b(j; p, n)$.

When one designs a single-stage trial to test hypothesis (1), once the parameters (p_0 , p_1 , α , β) are specified, the required sample size, n , and the critical point r at or above which to reject H_0 can be determined by a search over all possible (r, n) 's. For any given (r, n) , let $\beta(p) \equiv B(r-1; p, n)$, $\alpha' = 1 - \beta(p_0)$ and $\beta' = \beta(p_1)$. In practice, a small-sized n is used as the starting value, then the maximum value of X , say x , for which $\beta' \leq \beta$ is found; if $\alpha' \leq \alpha$ at x , n is retained and the critical point r is set equal to x , otherwise n is increased by 1 and the cycle is repeated. Note that due to the discrete nature of the binomial response variable α' and β' thus obtained may differ substantially in some cases from their nominal levels α and β .

For moderate to large samples, $z(p) = (\hat{p} - p) / [p(1-p)/n]^{1/2}$ follows approximately the standard normal distribution, where $\hat{p} = X/n$. One would then reject H_0 whenever $z(p_0) \geq z_{1-\alpha}$; that is, whenever $X \geq np_0 + z_{1-\alpha} \{np_0(1-p_0)\}^{1/2}$, where z_u denotes the u -quantile of the standard normal distribution. Due to the discreteness of the binomial distribution, the more appropriate critical value is (see Table 1 in Fleming^[2]):

$$r = \left[np_0 + z_{1-\alpha} \{np_0(1-p_0)\}^{1/2} \right]^* \quad (4)$$

where $[f]^*$ denotes the nearest integer to f . The sample size required to satisfy the error constraints on α and β is approximately (see Fleming^[2]):

$$n = \left\{ [z_{1-\beta}(p_1(1-p_1))^{1/2} + z_{1-\alpha}(p_0(1-p_0))^{1/2}] / (p_1 - p_0) \right\}^2 \quad (5)$$

When the sample size is small, the design based on the normal approximation can yield anomalous results (see A'Hern^[27]). The n obtained from the exact search is in general larger than that using the normal approximation.

Trinomial Response

Because hypotheses (3) and (3a) are essentially equivalent to hypothesis (2), we shall focus our discussion on testing hypothesis (2). Here the acceptance of H_0 is defined

by a two-dimensional region R of lattice points in the first quadrant, that is $R = \{(i, j) | 0 \leq i \leq I, 0 \leq j \leq Y_i, \text{ and } Y_1 > Y_2 > \dots > Y_I \geq 0\}$ where the first coordinate i refers to the number of CRs and the second coordinate j that of PRs (for a graphical depiction see Panageas et al.^[25]). The boundary of such a region can be represented as $\{(i, Y_i), 0 \leq i \leq I\}$, where I is the maximum number of CRs for which at least one point of the acceptance region R occurs, and Y_i is the maximum number of PRs in R at each value of j . Let x_c and x_p denote the numbers of observed CRs and of PRs, respectively, in n patients. The decision rule then is to accept H_0 if (x_c, x_p) falls on or below the boundary of R , otherwise the treatment is deemed effective and warranting further testing.

The mass trinomial probability function of observing x_c complete responses and x_p partial responses in n patients is given by:

$$t(x_c, x_p; p_c, p_p, n) = \frac{n!}{x_c! x_p! (n - x_c - x_p)!} p_c^{x_c} p_p^{x_p} (1 - p_c - p_p)^{n - x_c - x_p}$$

Let $\beta(p_c, p_p)$ denote the cumulative trinomial probability in the region R , that is,

$$\beta(p_c, p_p) \equiv P\{(x_c, x_p) \in R | (p_c, p_p)\} = \sum_{i=0}^I \sum_{j=0}^{Y_i} t(i, j; p_c, p_p, n) \quad (6)$$

Then, we can calculate the overall type I and type II errors as $\alpha' = 1 - \beta(p_{0c}, p_{0p})$ and $\beta' = \beta(p_{1c}, p_{1p})$ respectively. Similarly, one can define the acceptance region for testing hypothesis (3) or (3a), and calculate their associated error rates.

Given the parameters $(p_{0c}, p_{0p}, p_{1c}, p_{1p}, \alpha, \beta)$ or $(p_{0r}, p_{0p}, p_{1r}, p_{1p}, \alpha, \beta)$ for testing hypothesis (2) or (3) respectively, the key issue of the single-stage design for trinomial response is the determination of the total sample size required, n , and of the acceptance region R , subject to the error constraints α and β . Typically, the solution is obtained by an intensive search algorithm that enumerates over all feasible two-dimensional regions using exact trinomial probabilities. The search algorithms developed in^[24,25] for two-stage designs can be adapted to single-stage designs discussed here.

Lin and Chen^[28] considered the weighted-score method for testing hypothesis (2). Given x_c and x_p , the numbers of observed CRs and of PRs respectively in n patients, it can be shown that the likelihood ratio test criterion for testing a simple trinomial distribution against a simple alternative is a monotone function of the weighted score $s = \omega x_c + x_p$, where ω is a function of $(p_{0c}, p_{0p}, p_{1c}, p_{1p})$. This suggests the following decision rule: accept H_0 if s is at or below the critical value r ; otherwise the treatment is deemed effective and warranting further testing. The larger weight $\omega > 1$ for CR corresponds to $p_{1c}/(p_{1c} + p_{1p}) > p_{0c}/(p_{0c} + p_{0p})$, that

is, the proportion of CR among objective responses (OR = CR + PR) is greater under H_1 than under H_0 . This is consistent with the notion that if higher proportion of CR among OR indicates a more desirable outcome, then CR should be given more weight in deciding whether to accept or reject H_0 . Let $t_\omega(s; p_c, p_p, n)$ be the probability that the weighted score is s in n patients, that is

$$t_\omega(s; p_c, p_p, n) = \sum_{\omega x_c + x_p = s} t(x_c, x_p; p_c, p_p, n)$$

When ω is an integer different (x_c, x_p) 's may give rise to the same score s . In general, ω is a non-integer and each weighted score s is determined by a unique (x_c, x_p) pair, that is, there exists only one (x_c, x_p) pair such that $s = \omega x_c + x_p$. Let $\beta(p_c, p_p)$ denote the cumulative trinomial probability of observing a weighted score that is less than or equal to r in n patients, that is:

$$\beta(p_c, p_p) = \sum_{s \leq r} t_\omega(s; p_c, p_p, n)$$

Then, we can calculate the overall type I and type II errors as $\alpha' = 1 - \beta(p_{0c}, p_{0p})$ and $\beta' = \beta(p_{1c}, p_{1p})$ respectively. The weighted-score method translates the two dimensional search for the acceptance region to a one-dimensional search for the critical point, following the same search strategy for the binomial response model. After obtaining the critical point for the weighted score, it can be converted to the acceptance region in the two-dimensional space of (CR, PR)'s (see example below). It is easy to adapt algorithm developed in^[28] for two-stage designs to single-stage designs discussed here.

Example

For the binomial response with $(p_0, p_1, \alpha, \beta) = (0.3, 0.5, 0.05, 0.10)$, the single-stage design requires a sample size of 53, and if there are 22 or more responses then the treatment would be considered as effective to move on to Phase III trial. Using the weighted-score approach^[28] the single-stage design for the trinomial response with $(p_{0c}, p_{0p}, p_{1c}, p_{1p}, \alpha, \beta) = (0.1, 0.2, 0.2, 0.3, 0.05, 0.10)$ requires a sample size of 49 and a critical value of 22.90 of the weighted score with $\omega = 1.39$. This critical value defines an acceptance region in the two-dimensional space of (CR, PR)'s whose boundary consists the set of lattice points: $\{(0,22), (1,21), (2,20), (3,18), (4,17), (5,15), (6,14), (7,13), (8,11), (9,10), (10,9), (11,7), (12,6), (13,4), (14,3), (15,2), (16,0)\}$. For example, since (0,22) is on the boundary and (13,5) is above the boundary, one would conclude that the treatment is ineffective with 22 PRs, and effective with 13 CRs and 5 PRs. The weighted-score method is more efficient since it requires only 49 patients, less than 53 required by the design based on the binomial model.

MULTI-STAGE DESIGN

In a multi-stage design, patients are entered into the trial in stages; at the end of each stage, a decision based on the number of responses observed thus far is made either to stop the trial or to continue to the next stage. Thus the multi-stage design differs from the single-stage design in a simple but important way: in the single-stage design a fixed number of patients is accrued for the trial, whereas in the multi-stage design, although the maximum number of patients required is fixed, the actual number accrued can vary greatly, depending on the stage at which the trial is terminated. Hence, on average the sample size required in a multi-stage design will generally be smaller than that of the corresponding single-stage design. Most multi-stage designs, e.g., Simon's^[5] two-stage designs, aim to minimize the average sample size according to some optimization criterion. Others, such as Fleming's^[2] multi-stage designs, focus on controlling the spending of error rates among stages and are not based on any optimization criterion. Most multi-stage designs have been limited to two stages, mostly because the additional stages would cause too many unacceptable disruptions during the trial and the logistics of the trial may become too complicated and infeasible.

Binomial Response

We describe several widely used multi-stage designs for testing hypothesis (1). We also describe various modifications, improvements, and extensions recently published in the literature.

Gehan's Two-Stage Design

Gehan's^[1] design is only partially based on the hypothesis testing framework. It controls the error β of rejecting an effective treatment only at the first stage; the final sample size is determined by the precision requirement of estimation. It does not specify an undesirable response rate p_0 , which would be used to control the probability α of accepting an ineffective treatment.

In the first stage, n_1 patients are treated. The trial is terminated and the treatment is abandoned if x_1 , the number of responses, among the n_1 patients is zero. If there is at least one response ($x_1 \geq 1$), then the trial proceeds to the second stage by accruing n_2 additional patients to be treated. Let x_2 denote the number of responses among the n_2 patients. The goal is to obtain an estimator of the true response rate p whose standard error is within a pre-specified limit, σ .

In the first stage, n_1 is chosen to control the probability β (type II error) of abandoning the treatment when the true response rate is at the minimum desirable level p_1 . That is, $\beta \equiv \text{prob}(x_1 = 0 | p = p_1) = (1 - p_1)^{n_1}$. Hence, $n_1 = \log(\beta) / \log(1 - p_1)$. Given that n_1 thus obtained will in general not be an integer, in practice the sample size n_1

required for the first stage is set to be the next integer bigger than this solution. At the end of the trial, the estimate of the response rate is $\hat{p} = x/n$ and $\text{var}(\hat{p}) = p(1-p)/n$, where $x = x_1 + x_2$ and $n = n_1 + n_2$. The precision requirement, $\text{var}(\hat{p}) = \sigma^2$, implies that $n = n_1 + n_2 = p(1-p)/\sigma^2$. Because the true rate p is unknown, we estimate it by x_1/n_1 from the first stage sample, or as suggested in Gehan,^[1] by the more conservative upper 75% confidence limit for p based on the statistic x_1/n_1 .

The sample sizes n_1 and n_2 required for the Gehan's design can be easily obtained by the procedure described above. They are also available in Gehan^[1] for commonly used (β, p_1, σ) 's. As an example, if $(\beta, p_1, \sigma) = (0.05, 0.20, 0.1)$, then the first stage sample size is 14 and the maximum second stage sample size is 11 (note that $n = n_1 + n_2 = p(1-p)/(0.1)^2$ is maximized at $p = 0.50$ with $n_{\max} = 25$; hence $n_2 = 25 - 14 = 11$). If the number of responses at the first stage is $x_1 = 3$, then the upper 75% confidence limit derived from $x_1/n_1 = 3/14$ is 0.34, which gives rise to a total sample size $n = (0.34)(0.66)/(0.01) \approx 23$; hence $n_2 = 9$. On the other hand, if $x_1 = 4$, then a similar calculation leads to $n_2 = 11$.

Fleming Multi-Stage Design

Following O'Brien and Fleming^[29] for the two-sample situation, Fleming^[2] proposed a one sample multi-stage testing procedure for Phase II clinical trials. Let K be the number of stages, $(n_1, n_2, \dots, n_K)$ the number of patients accrued at each stage, $(r_1, r_2, \dots, r_K)$ the set of rejection points, and $(\alpha_1, \alpha_2, \dots, \alpha_K)$ a corresponding set of acceptance points. The acceptance and rejection points form the boundaries of a test region in which $\alpha_i < r_i$. At the terminal stage $\alpha_K = r_K - 1$, so that a decision in favor of or against H_0 is necessarily taken by the end the study. Let $s_j = \sum_{i=1}^j x_i$, where x_i is the number of responses among n_i patients. At the end of each stage, say, stage j , the decision rule is to stop the trial for effectiveness (reject H_0) if $s_j \geq r_j$, or ineffectiveness (accept H_0) if $s_j \leq \alpha_j$, or otherwise to continue the study to the next stage.

The total sample size $n \equiv n_1 + n_2 + \dots + n_K$ is determined by Eq. 5 and is then apportioned arbitrarily, in general equally, among the K stages. Hence, Fleming's^[2] design does not optimize with regard to the sample size within stages. The rejection and acceptance points are determined as follows:

$$r_j = \left\lceil \sum_{i=1}^j n_i p_0 + z_{1-\alpha} \{n p_0 (1 - p_0)\}^{1/2} \right\rceil + 1, j = 1, \dots, K \quad (7)$$

$$\alpha_j = \left\lfloor \sum_{i=1}^j n_i \tilde{p}_1 - z_{1-\alpha} \{n \tilde{p}_1 (1 - \tilde{p}_1)\}^{1/2} \right\rfloor, \quad j = 1, \dots, K-1 \quad (8)$$

where $\tilde{p}_1 = [(n p_0)^{1/2} + (1 - p_0)^{1/2} z_{1-\alpha}]^2 / (n + z_{1-\alpha}^2)$. Note that all r_j and α_j points here depend on the total sample size n .

They are obtained by adjusting the critical values for the standard single-stage test procedure based on the normal approximation. For example, r_j in Eq. 7 is obtained by replacing the standard critical value $z_{1-\alpha}$ for rejecting H_0 at the end of j th stage by $(n / \sum_{i=1}^j n_i)^{1/2} z_{1-\alpha}$. This adjustment makes H_0 difficult to reject at the early stages but easier later on. Since Eq. 7 coincides with Eq. 4 at the K th stage, the test at the end of the trial is performed as the single-stage design. The nominal type I and type II error levels of the single-stage procedure are essentially preserved whenever $K \leq 5$ (see Table 2 in Fleming^[2]).

Remark. Chang et al.^[30] have considered the same multiple testing problem as Fleming^[2] and produced designs that minimized the average of the average sample sizes under the null and alternative hypotheses. They proposed a likelihood ratio method to determine optimal decision boundaries when the sample size at each stage is given. This approach allows them to search for the optimal design from a restricted set without having to do an exhaustive search. In all cases they investigated the optimal design thus obtained was the true global optimum. They were also able to obtain the optimal allocation of sample sizes among K stages and corresponding optimal decision boundaries. They used multiples of 5 as sample size at each stage and presented optimized results for three-stage designs (see Tables 1–3 in Chang et al.^[30]).

Simon's Two-Stage Designs

Simon^[5] restricted the attention to two-stage designs due to practical considerations in the management of multi-center clinical trials. Unlike Fleming^[2] and Chang et al.,^[29] early termination in Simon's^[5] designs occurs for inefficacy only. Let (n_1, n_2) denote the numbers of patients accrued at the first and second stages, and (x_1, x_2) the corresponding numbers of responses observed. The decision rule for Simon's two-stage designs is: At stage 1, stop the trial and reject H_1 if $x_1 \leq r_1$, otherwise continue to stage 2; at stage 2, reject H_1 if $x_1 + x_2 \leq r_2$, otherwise reject H_0 . Here we refer to (r_1, r_2) as the rejection points of H_1 at the end of stage 1 and stage 2. In Fleming's^[2] design these critical values were referred to as acceptance points of H_0 and denoted as a_1 and a_2 .

Let $\beta_1(p)$ and $\beta_2(p)$ denote the probabilities of rejecting H_1 at the end of stages 1 and 2 respectively, that is,

$$\beta_1(p) = P[x_1 \leq r_1 | p] = B(r_1; p, n_1)$$

and

$$\begin{aligned} \beta_2(p) &= P[x_1 > r_1 \text{ and } x_1 + x_2 \leq r_2 | p] \\ &= \sum_{x=r_1+1}^{\min[n_1, r_2]} b(x; p, n_1) B(r_2 - x; p, n_2) \end{aligned}$$

The overall probability of rejecting H_1 is $\beta(p) = \beta_1(p) + \beta_2(p)$. Hence, the overall type I error is $\alpha' = 1 - \beta(p_0)$ and type II error is $\beta = \beta(p_1)$. The expected sample size required is $EN = n_1 + [1 - \beta_1(p)]n_2$.

Given $(p_0, p_1, \alpha, \beta)$, there are many (n_1, n_2, r_1, r_2) 's that satisfy the error constraints on α and β . Within these, the optimal design is the one with the minimum $EN(p_0)$, and the minimax design is the one that has the minimum total sample size n and within this fixed n it has the minimum $EN(p_0)$. By enumeration using exact binomial probabilities, Simon^[5] has described an extensive search procedure to determine both design solutions. Sample sizes and critical values for both optimal and minimax designs, expressed as $(r_1/n_1, r_2/n)$ with $r = r_2$ and $n = n_1 + n_2$, are available in Simon^[5] and also in Chow et al. (Tables 5.3.1 and 5.3.2 in Ref. [31]).

Remark 1. Although the optimal design has the minimum expected sample size, it requires a larger total sample size than the minimax design. In some cases, especially when the patient accrual rate is low, an alternative design between the minimax and optimal designs may be more attractive if its expected sample size (EN) is close to that of the optimal design but with much smaller total sample size than the optimal design. Due to the discreteness of the binomial distribution such alternative designs often exist and can be identified by comparing minimum EN for each n between that of the minimax design and that of the optimal design (or any accruable sample size). Jung et al.^[32] suggested a graphical method to help search for such an alternative design.

Remark 2. Hanfelt et al.^[33] have argued that the relevance of Simon's optimal design depends to some extent on the size of a given institution's program of Phase II trials. If an institution conducts a large number of independent Phase II trials, then it makes sense trying to minimize the average sample size required. They proposed a modification to Simon's optimal design with the objective of minimizing the median sample size. The modified design is appropriate at institutions conducting one or a small number of Phase II trials. The modified optimal design tends to be identical to the Simon's optimal design when the hypothesized response rates are small. In most other cases, the modified design substantially reduces the median sample size. It also tends to have a smaller initial cohort of patients (n_1) than under Simon's design. Generally, the modified design has an expected sample size that exceeds that of Simon's design by one or two patients.

Remark 3. Like Fleming^[2] and Chang et al.,^[30] Shuster^[34] has considered the decision problem where one is allowed to stop the trial at the end of the first stage, either for significance or for non-significance of response rate. This feature is important in some clinical trial settings, such

as Phase II pediatric cancer trials, in which it is in the patients' and investigators' best interests to allow early termination of trials for efficacy. Because one will never know the true value of the response probability p , Shuster proposed a two-stage minimax design that minimizes the globally maximized expected sample size. When early stopping due to significance is not allowed and $p = 1$ (guaranteed response), the trial continues to the second stage and the globally maximized expected sample size reduces to the total sample size. Hence, Shuster's minimax design includes Simon's minimax design as a special case. This new minimax design has lower average sample size than Simon's optimal design under the alternative and at the global maximum. (Note: Simon's^[5] optimal design has minimum average sample size under the null p_0).

Remark 4. At the end of the trial a decision can be made about whether the therapy warrants further evaluation, but an estimate of the true probability of response may also be desired. However, the naïvely used MLE estimator $\hat{p} = (x_1 + x_2)/n$ is generally biased because it does not account for the stopping rule (see Ref. [35]). Jung and Kim^[9] evaluated the uniformly minimum variance unbiased estimator (UMVUE) of p when used with Simon's optimal and minimax designs. They found that the MLE is generally more biased with optimal than minimax designs, and that the bias of the MLE is greatest when $p_0 < p < p_1$; although they did not encounter bias < -0.03 , this difference could be important in subsequent trial design with target effect size of 0.15 to 0.20. They also found some efficiency loss for the UMVUE relative to the MLE, but pointed out that bias is the bigger problem. In a related article, Jung et al.^[11] discussed the issue of p -value calculation at the end of the trial. Koyama and Chen^[12] discussed estimation and p -value calculation when the actual number of patients enrolled deviates from the planned.

Remark 5. Recently, Jung^[14] has proposed a randomized analog of the Simon's two-stage optimal and minimax designs with a concurrent control arm. Sample size in each treatment arm is comparable to that of a single arm trial, thus the overall sample size of the trial is approximately twice that of a single arm study. In order to keep the sample size reasonably small and not to preclude a definitive randomized Phase III trial, they suggest using α of 0.15 or 0.20 and β of 0.20.

Three-Stage Designs

Chen^[36] extended both the optimal and minimax two-stage designs in Simon^[5] to three-stage designs. For the case of an ineffective treatment, this extension can reduce the expected sample size by an average of 10% from that of a two-stage design. The three-stage design is useful when

accrual is slow, so that the temporary suspension of the study and examination of cumulative data does not create an onerous administrative burden.

The decision rule for stopping or continuing the study is as follows: At stage 1, stop and reject H_1 if $x_1 \leq r_1$, otherwise continue to stage 2; at stage 2, stop and reject H_1 if $x_1 + x_2 \leq r_2$, otherwise continue to stage 3; at stage 3, reject H_1 if $x_1 + x_2 + x_3 \leq r_3$, otherwise reject H_0 . Let $\beta_1(p)$, $\beta_2(p)$ and $\beta_3(p)$ denote the probabilities of rejecting H_1 at the end of stages 1, 2, and 3 respectively, that is,

$$\begin{aligned}\beta_1(p) &= P[x_1 \leq r_1 | p] = B(r_1; p, n_1) \\ \beta_2(p) &= P[x_1 > r_1 \text{ and } x_1 + x_2 \leq r_2 | p] \\ &= \sum_{x_1=r_1+1}^{\min[n_1, r_2]} b(x_1; p, n_1) B(r_2 - x_1; p, n_2)\end{aligned}$$

and

$$\begin{aligned}\beta_3(p) &= P[x_1 > r_1, x_1 + x_2 > r_2 \text{ and } x_1 + x_2 + x_3 \leq r_3 | p] \\ &= \sum_{x_1=r_1+1}^{\min[n_1, r_2]} \sum_{x_2=r_2+1-x_1}^{\min[n_2, r_3-x_1]} b(x_1; p, n_1) b(x_2; p, n_2) \\ &\quad \times B(r_3 - x_1 - x_2; p, n_3).\end{aligned}$$

The overall probability of rejecting H_1 is $\beta(p) = \beta_1(p) + \beta_2(p) + \beta_3(p)$. Hence, the overall type I and type II errors are $\alpha' = 1 - \beta(p_0)$ and $\beta = \beta(p_1)$ respectively. The expected sample size required is $EN(p) = n_1 + (1 - \beta_1(p))n_2 + (1 - \beta_1(p) - \beta_2(p))n_3$.

Given $(p_0, p_1, \alpha, \beta)$, there are many $(r_1, n_1, r_2, n_2, r_3, n_3)$'s that satisfy the error constraints on α and β . Among them, the optimal solution is the one with the minimum $EN(p_0)$, and the minimax solution is the one that has the minimum total sample size n and within this fixed n has the minimum $EN(p_0)$. Chen^[36] wrote a FORTRAN program to search exhaustively for these two solutions based on enumeration of exact binomial probabilities. Sample sizes and critical values under a variety of design parameters are available in Chen (Tables I–IV in Ref. [36]) and also in Chow et al. (Tables 5.3.9–5.3.12 in Ref. [31]).

Ensign et al.^[6] have observed that Simon's^[5] optimal two-stage design does not allow early termination when there are many failures at the start. Therefore, motivated by ethical reasons to reduce the number of patients receiving treatment with very low response rate, they proposed a three-stage design as a combination of the first stage in Gehan's^[1] design and Simon's^[5] optimal two-stage design. This design can be viewed as a special case of Chen's^[36] optimal three-stage design with the first stage sample size n_1 set to be at least 5 and the rejection point r_1 to be 0. Sample sizes and critical values of Ensign et al.'s^[6] optimal three-stage designs, under a variety of design parameters,

are available in Ensign et al. (Tables 1 and 2 in Ref. [6]) and also in Chow et al. (Tables 5.3.7 and 5.3.8 in Ref. [31]). Chen^[36] corrected errors in many entries of these tables. In general, the average sample size of Ensign et al.'s^[6] optimal three-stage design is smaller than that of Simon's optimal two-stage design, although the maximum sample size can be smaller or larger when $p_0 \leq 0.30$. It has the greatest utility when the true response rate of the treatment is low. However, the restrictions on (r_1, n_1) increase $EN(p_0)$ and make the first stage redundant for large p_0 .

Flexible Designs

In the cooperative group setting consisting of many centers, practical considerations make it difficult to arrive at the planned sample size exactly. Sometimes, the patient accrual may fall short of the required sample size; other times, a center would have to accept more patients even though their original quota of patients has been met. In such cases, actual sample size at each stage can deviate slightly from the exact design. To overcome such difficulties, Green and Dahlberg^[37] have proposed various adaptive two-stage designs to address the decision-making issues based on the attained or actual sample sizes in each stage, not the planned sample size. Herndon^[38] has proposed a two-stage design that allows patient accrual to continue while the results of the first stage are reviewed. Unlike Simon's optimal and minimax designs, these designs do not aim to minimize the number of patients tested on an ineffective treatment.

Chen and Ng^[39] have proposed a flexible design as a collection of two-stage designs where the first stage size is in a set of consecutive values $(n_1, \dots, n_k)$ and the total sample size is also in another set of consecutive values $(N_1, \dots, N_k)$, and each of k^2 possible designs has the same probability of occurrence. Denote the critical value for the first stage as r_i when the sample size is n_i , and for the second stage as R_j when the sample size is N_j . Each member, say (r_i, n_i, R_j, N_j) , of the design collection follows the same decision rule as Simon's two-stage designs, that is as follows: At stage 1, stop and reject H_1 if there are r_i or fewer responses in the n_i patients, otherwise continue to stage 2; at stage 2, reject H_1 if there are R_j or fewer responses out of N_j patients, otherwise reject H_0 and conclude that the treatment is a candidate for further testing. For each member design, type I and type II errors and expected sample size (EN) are defined as in the Simon's two-stage design. Type I and type II errors and EN of the flexible design are then defined as the average of these respective measures over all members within the collection. There are many collections of (r_i, n_i, R_j, N_j) 's that satisfy the α and β constraints. The optimal flexible design is the one that has the minimum average EN when $p = p_0$. The minimax flexible design is the one that has the minimum N_k , and the minimum average EN within this fixed N_k when $p = p_0$. In application, $k = 8$ is suggested

with target sizes at the middle of ranges. Tables providing sample sizes and critical values for flexible two-stage optimal designs and minimax designs are available in Chen and Ng (Tables I–IV in Ref. [39]) and also in Chow et al. (Tables 5.3.3–5.3.6 in Ref. [31]). Masaki et al. [40] proposed an extension of Chen and Ng's method in which the actual sample size is allowed to deviate from the planned sample size symmetrically by up to two, and the probability of a given sample size decreases as it deviates from the target sample size.

Remark. Instead of the average, it would seem reasonable to define the error rates and EN of a flexible design as the median or maximum of these measures within the collection. However, the statistical property of using these different criteria would need to be further studied.

Designs that Jointly Evaluate Efficacy and Toxicity

For some treatments, evaluation of toxicity is equally important to assessment of efficacy, and it is desirable to incorporate toxicity monitoring into the early stopping rule of the trial. Recognizing this need, Bryant and Day^[41] proposed two-stage designs, similar in structure to Simon's^[5] optimal two-stage designs, which jointly evaluate clinical response and toxicity. From current treatment results, both undesirable and desirable levels for the true response rate p_r , (p_{0r}, p_{1r}) , and for the true non-toxicity rate p_t , (p_{0t}, p_{1t}) , are specified. The null hypothesis $H_0: p_r \leq p_{0r}$ or $p_t \leq p_{0t}$ is to be tested against the alternative hypothesis $H_1: p_r \geq p_{1r}$ and $p_t \geq p_{1t}$.

Let (n_1, n_2) denote the numbers of patients accrued at the first and second stages, (x_1, x_2) be the corresponding numbers of clinical responses, and (y_1, y_2) be that of patients who do not experience toxicity. The decision rule for the trial is as follows: At stage 1, stop the trial and reject H_1 if either $x_1 \leq r_1$ or $y_1 \leq t_1$, otherwise continue to stage 2; at stage 2, reject H_1 if either $x_1 + x_2 \leq r_2$ or $y_1 + y_2 \leq t_2$, otherwise reject H_0 and recommend the treatment for further testing. The probabilities of rejecting at the end of stages 1 and 2 respectively and the expected sample size (EN) required are evaluated (Eqs. 4.6–4.9 in Bryant and Day^[41]), based on the joint distribution of response and toxicity under various assumptions on the bivariate association. Type I errors at (p_{0r}, p_{1r}) and (p_{1r}, p_{0r}) are subjected to constraints α_r and α_t . Given $(p_{0r}, p_{1r}, p_{0t}, p_{1t}, \alpha_r, \alpha_t, \beta)$, there are many $(n_1, n_2, r_1, r_2, t_1, t_2)$'s that satisfy the error constraints on α_r, α_t and β . Within these, the optimal solution is the one that minimizes $\max_{\phi > 0} \max \{E_{01}(\phi), E_{10}(\phi)\}$, where ϕ is an unspecified association parameter, and $E_{01}(\phi)$ and $E_{10}(\phi)$ denote EN evaluated at (p_{0r}, p_{1r}) and (p_{1r}, p_{0r}) , respectively, under ϕ . Bryant and Day^[41] provide a table for sample sizes and critical points under a limited set of design parameters. The $\max \{E_{01}, E_{10}\}$ is always bigger than the corresponding EN from the Simon's optimal two-stage design, reflecting the additional cost of addressing the uncertainty in toxicity.

Remark. Conaway and Petroni^[42] and Thall and Cheng^[43] have also considered multi-stage designs to monitor anti-tumor activity and toxicity. Unlike,^[41] designs proposed in Ref. [42] controlled type I error at (p_{0r}, p_{0r}) and at the maximum over the entire null hypothesis region. Exhaustive search algorithm based on enumeration of exact bivariate binomial probabilities was used in Refs. [41,42] to search for the optimal designs. On the other hand, optimal two-stage designs developed in Ref. [43] were based on normal theory, using the arcsin square-root transformations on the bivariate binomial probabilities. Designs for the Phase II trials allowing for a trade-off between response and toxicity was addressed in Refs. [43,44].

Randomized Discontinuation Design

Randomized discontinuation design (RDD) is a two-stage design in which all enrolled patients receive the experimental treatment in the first stage, and a subset of patients is selected at the end of the first-stage based on response to treatment. In the second stage, only this subset of patients are randomized to continue their current treatment or to switch to placebo. This design is an example of an enrichment design, in which the objective is to select a more homogeneous group of patients who are likely to show benefit from treatment and to exclude others who may dilute the effect if it exists. For example, an RDD can be used to study the effects of a long-term cytotoxic therapy,^[45] where patients responding after the first stage are randomized, and those with stable or progressive disease are taken off study. More recently, however, RDD has been proposed as an alternative Phase II trial design for the study of molecular targeted (cytostatic) agents in an attempt to identify a subpopulation that may have a clinical benefit without experiencing objective response. An example of this is a trial in renal cell cancer^[16] in which patients with stable disease (SD) at the end of the first stage were randomized to discontinue therapy, whereas responders and patients with progressive disease were taken off study (responders were allowed to continue treatment for ethical reasons). Different types of endpoints, such as response rate with longer therapy, proportion of patients with progressive disease, or time to disease progression, can be used to compare the randomized treatment arms at the end of the second stage.

Power and sample size for RDDs are usually determined using simulations. For response or progression endpoints, tumor size data can be generated using a tumor growth model,^[46] and changes in tumor size at a fixed time point can be classified as response, stable disease or progression. For time to event endpoints, either a tumor growth model or Weibull distribution can be used to generate event times. Compared to clinical trials with upfront randomization, Freidlin and Simon^[48] and Fu et al.^[47] found some scenarios where RDD is more efficient, especially if the proportion of “sensitive” patients (e.g., patients who express the presumed molecular target of the agent) is relatively small

in the population and no reliable assay for identifying such patients otherwise is available. They note, however, that their conclusions are sensitive to the data generating model.

Although the RDD has been proposed as an alternative trial design for targeted cytostatic agents, some of its disadvantages include complicated interpretation of the results and estimation, and potentially biased results due to the unexpected carry-over effect. Finally, if the proportion of sensitive patients and the effect size are both small, both the RDD and the upfront-randomized Phase II trials may require too large a sample size to be feasible.

Trinomial Response

A multi-stage design for trinomial response can be considered as an extension of a single-stage design for trinomial response or of a multi-stage design for binomial response. Lin and Chen^[28] and Panageas et al.^[24] extended Simon's^[5] two-stage designs for binomial response to trinomial response where complete and partial responses are differentiated. On the other hand, Zee et al.,^[25] Dent et al.,^[48] and Freidlin et al.^[26] extended Fleming's^[2] multi-stage design to trinomial response where stable disease and disease progression are differentiated.

The various hypotheses for trinomial response have been described in the section “Trinomial Response.” We shall focus on testing hypothesis (2). Let (n_1, n_2) denote the numbers of patients accrued at the first and second stages and let $n = n_1 + n_2$. Also let x_{1c} and x_{1p} denote the numbers of CRs and PRs respectively among n_1 patients, and x_c and x_p the numbers of CRs and PRs respectively among n patients. The decision rule for the trial is based on acceptance regions R_1 and R . Each of these regions is defined as in section “Single-Stage Design.” At the end of the first stage, if the (x_{1c}, x_{1p}) pair falls in the region R_1 , the trial will be terminated early. If the pair falls above the region, the trial will proceed to the second stage. At the end of the second stage, if the (x_c, x_p) pair falls in the region $R_2 = R - R_1$, then the treatment will be deemed ineffective. If it falls anywhere above the region R , the treatment will be recommended for further testing.

Let $\beta_1(p_c, p_p)$ and $\beta_2(p_c, p_p)$ denote the cumulative trinomial probabilities in the regions R_1 and R_2 respectively. These probabilities can be obtained by replacing R in Eq. 6 with R_1 and R_2 respectively. Let $\beta(p_c, p_p) = \beta_1(p_c, p_p) + \beta_2(p_c, p_p)$. Then the overall type I and type II errors are $\alpha' = 1 - \beta(p_{0c}, p_{0p})$ and $\beta' = \beta(p_{1c}, p_{1p})$. The expected sample size required is $EN(p_c, p_p) = n_1 + [1 - \beta_1(p_c, p_p)]n_2$. Given the parameters $(p_{0c}, p_{0p}, p_{1c}, p_{1p}, \alpha, \beta)$, the design problem involves finding both regions R_1 and R , subject to error constraints α and β . Among all feasible (R_1, R) 's the optimal design is the one with the minimum $EN(p_{0c}, p_{0p})$, and the minimax design is the one with the minimum total sample size n , and within this fixed n with the minimum $EN(p_{0c}, p_{0p})$. Optimal and minimax designs can be obtained using exhaustive search

algorithm based on enumeration of exact trinomial probabilities. Such algorithm is computationally highly intensive. Panageas et al.^[24] considered only optimal designs and tabulated sample sizes and boundaries of R_1 and R under a variety of design parameters.

Lin and Chen^[28] used the weighted-score approach to differentiate between the complete and partial responses. From the number of complete responses x_c and the number of partial responses x_p , a weighed score $s^* = \omega x_c + x_p$, $\omega > 1$, is computed. The decision rule is as follows: At stage 1, if the weighted score of responses among n_1 patients is s_1 or less, the study is terminated and the treatment is declared to be ineffective. Otherwise, the trial is continued to stage 2. At stage 2, if the weighted score out of n patients is s or less, the study is terminated and the treatment is declared ineffective. Otherwise, the treatment warrants to be tested further.

Let $\beta_1(p_c, p_p)$ and $\beta_2(p_c, p_p)$ denote the probabilities of rejecting H_1 at the end of stage 1 and stage 2 respectively, that is

$$\beta_1(p_c, p_p) \equiv T_\omega(s_1; p_c, p_p, n_1) = \sum_{s^* \leq s_1} t_\omega(s^*; p_c, p_p, n_1).$$

and

$$\beta_2(p_c, p_p) = \sum_{s_1 < s^* \leq \min[\omega n_1, s]} t_\omega(s^*; p_c, p_p, n_1) T_\omega(s - s^*; p_c, p_p, n_2).$$

The overall probability of rejecting a treatment is $\beta(p_c, p_p) = \beta_1(p_c, p_p) + \beta_2(p_c, p_p)$. Hence, the overall type I and type II errors are $\alpha' = 1 - \beta(p_{0c}, p_{0p})$ and $\beta' = \beta(p_{1c}, p_{1p})$ respectively. The expected sample size $EN = n_1 + [1 - \beta_1(p_c, p_p)]n_2$.

There are many $(s_1/n_1, s/n)$'s which satisfy α and β requirements for a specific $(p_{0c}, p_{0p}, p_{1c}, p_{1p})$. Within these the optimal solution is defined as the one which has the minimum EN when $p_c = p_{0c}$ and $p_p = p_{0p}$. A minimax solution is the one which has the minimum n , and within this fixed n the minimum EN when $p_c = p_{0c}$ and $p_p = p_{0p}$. An extensive search procedure based on exact calculation of trinomial probabilities is used to find the optimal and minimax designs. As indicated in the single-stage design, the weighted-score method only needs to search for the critical values s_1 and s which can then be used to determine boundaries of acceptance regions R_1 and R respectively. Hence, the search based on weighted score is computationally much less intensive compared to the two-dimensional search of Panageas et al.^[24] Design solutions $(s_1/n_1, s/n)$'s under a variety of design parameters are available in Lin and Chen (Tables I and II in Ref. [28]).

Example: Given $(p_{0c}, p_{0p}, p_{1c}, p_{1p}) = (0.033, 0.067, 0.12, 0.18)$ and $(\alpha, \beta) = (0.10, 0.10)$, the optimal two-stage design of Panageas et al.^[24] gives rise to $n_1 = 13$, $n = 29$, $EN(p_{0c}, p_{0p}) = 19.06$, and acceptance regions R_1 and R

with boundaries $\{(0,1), (1,0)\}$ and $\{(0,5), (1,4), (2,2), (3,1)\}$ respectively. On the other hand, the optimal two-stage design based on the weighted score approach of Lin and Chen^[28] gives rise to $(s_1/n_1, s/n) = (1.23/13, 5.23/29)$ and $EN(p_{0c}, p_{0p}) = 19.06$, where scores s_1 and s are computed with weight $\omega = 1.23$. The scores $s_1 = 1.23$ and $s = 5.23$ determine respectively the boundaries of acceptance regions R_1 and R to be $\{(0,1), (1,0)\}$ and $\{(0,5), (1,4), (2,2), (3,1), (4,0)\}$. Both approaches have the same n_1 , n , $EN(p_{0c}, p_{0p})$, and R_1 . However, the weighted-score approach includes an additional boundary point (4,0) in the acceptance region R . Hence, with four CRs one would conclude that the treatment is effective under the design of Panageas et al.^[24] but ineffective under the design based on the weighted score approach. Both designs are more efficient than Simon's two-stage optimal design when CR and PR rates are combined (summed) which requires $n_1 = 12$, $n = 35$ with $EN(p_0) = 19.84$.

Multi-stage design for testing hypothesis (3) was originally proposed by Zee et al.^[25] and was applied in Phase II trials by Dent et al.^[48] Such design extends Fleming's^[2] design that focuses on controlling the spending of the error rate among stages and is not based on any optimization criterion with respect to the average sample size. Zee et al.^[25] also use exhaustive search algorithm to obtain the design solution. As indicated earlier, hypothesis (3) is pragmatically equivalent to hypothesis (3a), and hypothesis (3a) is mathematically equivalent to hypothesis (2). Hence, the designs discussed above for hypothesis (2) are applicable for either hypothesis (3) or (3a).

Kocherginsky et al.^[49] used a similar approach to design a two-stage trial which satisfies α and β constraints for multiple alternative hypotheses chosen to represent different scenarios of what would be considered drug activity. More specifically, they chose four alternative hypotheses to represent (i) a clinically meaningful increase in response rate and no change in early progression relative to H_0 , (ii) no change in response rate and a clinically meaningful decrease in progression rate only, (iii) moderate improvement in both response and progression rates, and (iv) strong improvement in both response and progression. For practical considerations, the overall sample size was chosen to match Simon's optimal design for testing H_0 vs alternative hypothesis (i), and an exhaustive search was used. The design minimizing the expected sample size was then chosen among all designs satisfying α and β constraints for multiple alternative hypotheses.

Sun et al.^[15] proposed a randomized multi-stage clinical trial for trinomial outcome, and also consider multiple alternative hypotheses representing activity in either endpoint (response or early progression)

$$H_{A1} : p_T > p_C \quad \text{and} \quad q_T = q_C$$

$$H_{A2} : p_T = p_C \quad \text{and} \quad q_T < q_C$$

$$H_{A3} : p_T > p_C \quad \text{and} \quad q_T < q_C$$

where p_T and p_C are response rates in treatment (T) and control (C) arms, and q_T and q_C are the respective progression rates. In this design, $2n_1$ patients are randomized during the first stage, and the decision to continue to stage 2 is based on satisfying either of the following mutually exclusive conditions:

Condition1: $X_{1T} - X_{1C} \geq D_1$ and $Y_{1T} - Y_{1C} < D_1 / 2$

Condition2: $-D_1 / 2 < X_{1T} - X_{1C} < D_1$ and $Y_{1T} - Y_{1C} \leq -D_1$

where X_{1T} and X_{1C} represent the number of responses in T and C arms at the end of stage 1, Y_{1T} and Y_{1C} represent the number of early progressions, cutoff D_1 is a boundary parameter of the design, and cutoff $D_1/2$ serves as the non-inferiority margin. If the trial continues to stage 2, an additional n_2 patients are enrolled in each treatment arm, and a similar decision rule is applied at the end of the trial with different cutoff D_2 . For this design, the total sample size needed to detect a 0.20 difference in response and progression rates between the treatment arms ranges between 46–58 for $\alpha = 0.20$ and $\beta = 0.20$ under H_{A3} , and larger sample sizes will be required if all three alternative hypotheses are to maintain $\beta = 0.20$.

CONCLUSION

For ethical reasons, multi-stage designs have become indispensable in conducting Phase II cancer trials. The most important feature of such designs is that they allow for early termination when the treatment is ineffective (or effective in some trial settings). As a consequence, the average sample size is reduced even without formal optimization with respect to the sample size within stages. However, most multi-stage designs were developed with the specific goal to optimize efficiency of the trial.

The gain in efficiency of a multi-stage design does not come without cost. For example, problems and difficulties are encountered with the suspension of patient accrual at the end of each stage of a trial. During the accrual down time, the interest and enthusiasm of participating investigators may wane, and accrual momentum during the subsequent stage of the study suffers. Thus, multi-stage designs with more than three stages are usually not recommended.

Even with only two stages, study suspensions in multi-stage designs can result in the actual (attained) sample size being different from the planned sample size, especially in multi-center studies. Thus, development of designs with greater flexibility and innovation, with improved statistical properties and practical considerations is an important area that requires further research. Other important areas for further research include possible extensions, modifications, or improvements on designs based on trinomial response and designs that jointly evaluate efficacy and toxicity.

Although efficient designs that address ethical concerns are important for Phase II cancer trials, many factors, such as deviations from planned sample sizes or proper analysis and inference in the end of the trial, may influence outcome and the decision on whether to proceed to a Phase III trial. These and other issues specific to the scientific context of the disease and experimental agent need to be discussed among clinical investigators and biostatisticians conducting the trials.

Selection of the primary endpoint has become an important factor in clinical trial design due to the development of targeted molecular therapies. Tumor response may no longer be an appropriate endpoint for trials involving such agents because their mechanism of action, which is inhibition of tumor growth or disruption of other cellular processes, may lead to clinical benefit without tumor response. Several innovative clinical trial designs and general guidance on choosing the primary endpoint have been recently discussed in the literature,^[19,20,50] but this remains an active research area.

Finally, although investigators are becoming more aware of the necessity for rigorous statistical methods, the number of Phase II studies that report a statistical plan is still disappointingly low (19.7% and 35.2% as reported in Refs. [7] and [8], respectively), which leads to concerns about the quality of such studies. We hope that this review of multiple-stage designs for phase II cancer trials will help investigators to better understand and appreciate the issues involved in phase II clinical trial design and conduct, and will guide them in making a proper choice among the many available designs.

Abstract

Multiplicative intensity (MI) models are used to analyze recurrent event data, where subjects repeatedly experience an event, or events of various types, throughout the study. This entry discusses the Andersen-Gill model of multiplicative intensity, the most commonly used model.

INTRODUCTION

Multiplicative intensity (MI) models are used to analyze recurrent event data, where subjects repeatedly experience an event, or events of various types, throughout the study, for example, a certain type of tumor (or different types of tumors) occurring in laboratory animals under observation over a period of time. In such situations, the objective of the analysis is to estimate the rate (intensity) at which the events occur and the effect of certain covariates on the intensity.

Multiplicative intensity models are extensions of Cox's proportional hazards model,^[1] in that they allow multiple events per subject and time-dependent covariates. Multiplicative intensity models were first introduced in their simplest form by Aalen.^[2] Then Anderson and Gill^[3] extended the models to apply to situations where the intensity function can have time-dependent and/or time-independent covariates. Since these seminal papers were published, MI models have been used in many applications and extended in many directions. For example, Tuli and coworkers^[4] used an MI model to analyze the repeated failures of shunts from three different causes among children with hydrocephalus. Hussein and Carrière^[5] used an MI model to identify covariates that cause discontinuity of care among a cohort of patients. Lin et al.^[6] used an MI model to identify factors contributing to motorcycle crashes among junior college students.

In this entry, we discuss the most commonly used MI model, i.e., the Andersen-Gill model. For detailed theoretical developments and practical applications, see Refs. [7–9].

THE MULTIPLICATIVE INTENSITY MODEL AND NOTATIONS

Consider recurrent event data collected from n subjects. Let $N_{hi}(t)$ be the number of type h events that have occurred to

the i th subject over a time period $(0, t]$. This is a counting process in the sense that it keeps its value until the type h event happens to the i th individual, at which time it adds 1 (a jump with size equal to 1) to its previous value. Therefore, at any given time t , the difference between the value of the processes at that time ($N_{hi}(t)$) and its value right before that time ($N_{hi}(t^-)$) is either 0 or 1. We denote this counting process at time t by

$$dN_{hi}(t) = N_{hi}(t) - N_{hi}(t^-) \quad (1)$$

assuming that the events are counted for each subject from a well determined origin of time. The origin can be the beginning of the study if all subjects were randomized at the same time. If subjects enter the study at staggered times and are randomized at their entry time, the origin for each subject could be the subject's actual time of entry. Also, we assume that no subject is observed (followed) after time τ , so that the study duration is $[0, \tau]$. In that period of time, the times of events and the subject's relevant covariate information are recorded. Assume that the counting processes are 0 at time 0 and that no two processes jump at the same time, i.e., $N_{hi}(0) = 0$ for all h and i , and there are no tied event times. If ties occur, some conditions are needed to ensure that the processes $N_{hi}(t)$ form a multivariate counting process, and to apply all theoretical inferences developed for the MI model. One could add a small amount such as 0.01 to displace the tied event times or apply the usual tie-handling methods such as the Breslow, Efron, or exact methods used for Cox's proportional hazards model, available in both SAS and Splus.

Let $Y_{hi}(t)$ be a risk indicator process having a value of 1 if the i th subject is under observation and at risk of suffering from the type h event just before t , and a value of 0 otherwise. Unlike the death-censoring indicator in the usual one-event (death) survival analysis, the process $Y_{hi}(t)$ allows subjects to be in and out of risk. For example, a patient hospitalized for a workplace-related injury is not at

risk of suffering from workplace-related injury during hospitalization. Thus, $Y_{hi}(t)$ for such a patient is 0 just before release from hospital and 1 afterwards.

Define $z_{hi}(t)$ as the type h event specific covariate process for the i th subject. Also, let $H(t)$ denote the history containing all available information about the three processes N , z , and Y up to time t . The covariate process $z(t)$ and the risk indicator process $Y(t)$ are assumed to be *predictable*. This means that their values at time t are fixed once the history is given up to but not including t , i.e., $H(t^-)$. The predictability condition for the covariates entails allowing no measurements at the time when an event takes place.^[10] This condition excludes the so-called internal time-dependent covariates.

Now that we have defined the processes N , z , Y , and the history H , we can define the functions of the MI model. The process $\lambda_{hi}(t, \theta)$ is called the intensity function of $N_{hi}(t)$, if the probability that $N_{hi}(t)$ has a jump in the small (infinitesimal) interval $(t^-, t]$ of length dt , given the history up to t^- , is approximately $\lambda_{hi}(t, \theta)dt$, so that

$$P[N_{hi}(t) - N_{hi}(t^-) = 1 | H(t^-)] \approx \lambda_{hi}(t, \theta)dt \quad (2)$$

or, equivalently, the expected jump in that interval given the history up to t^- is approximately $\lambda_{hi}(t, \theta)dt$, so that

$$E[N_{hi}(t) - N_{hi}(t^-) | H(t^-)] \approx \lambda_{hi}(t, \theta)dt \quad (3)$$

It follows from this definition that the process

$$M_{hi}(t) = N_{hi}(t) - \int_0^t \lambda_{hi}(s, \theta)ds \quad (4)$$

is a martingale. Loosely speaking, a martingale is a stochastic process whose expected value in the future, given “history” up to the present, is equal to its present value.

Equivalently, one could start from the martingale property to define intensity and say that the intensity of $N_{hi}(t)$ is a predictable process $\lambda_{hi}(t, \theta)$, such that (4) is a martingale. In addition to the above, one would also require the process

$$\Lambda_{hi}(t) = \int_0^t \lambda_{hi}(s; \theta)ds \quad (5)$$

to be “locally bounded.”

Under this setup, we say that the counting process $N_{hi}(t)$ follows a multiplicative intensity model if its intensity function is given by

$$\lambda_{hi}(t, \theta) = \alpha_{h0}(t, \gamma)Y_{hi}(t)e^{\beta'z_{hi}(t)} \quad (6)$$

where $\theta = (\gamma', \beta')'$. The term $e^{\beta'z_{hi}(t)}$ can be replaced by any positive function $f(t, z_{hi}(t))$, although the exponential

function is most commonly used (see Ref. [11] for other forms of f). The risk indicators $Y_{hi}(t)$ ensure that the subject is currently under observation and at risk of suffering from a type h event just before time t , in which case $Y_{hi}(t)$ has a value of 1 and hence does not contribute anything to the product in (6). The function $\alpha_{h0}(t, \gamma)$ is called a baseline intensity and is a non-negative function of some unknown parameters γ . It is interpreted as the probability of a type h event occurring to a subject at time t even in the absence of a covariate effect.

Note that the dependence of the intensity on the past of the event process, i.e., $N_{hi}(t^-)$, which is included in the past history $H(t^-)$, does not appear explicitly in Eq. (6). It is, however, implicitly assumed that such dependence is incorporated via time-dependent covariates $z(t)$. In general, the dependence structure among recurrent events is not easy to incorporate into the model, especially when attempting to accommodate them through $z(t)$. One alternative is to include the number of past events as time varying covariates, although there are no simple interpretations of these parameters. In practice, many analysts have neglected modeling this dependence, effectively assuming that the multiple events within a subject are independent. However, using this assumption leads to a mis-specified MI model. In such cases, the use of robust variance estimates could recover some of the lost efficiency.

The quantities

$$\Lambda_{hi}(t, \theta) = \int_0^t \lambda_{hi}(s, \theta)ds \quad (7)$$

and

$$A_{h0}(t, \gamma) = \int_0^t \alpha_{h0}(s, \gamma)ds \quad (8)$$

are called cumulative intensity and cumulative baseline intensity functions, respectively. By taking expectation for both sides of (4) and noting that the martingale will have an expected value of 0, they can be interpreted as the number of type h events expected to occur to the i th subject in $[0, t]$ in the presence or absence, respectively, of covariates.

Parametric Multiplicative Intensity Models

The MI model is parametric if, apart from the γ in (6), the functions $\alpha_{h0}(t, \gamma)$ and $z_{hi}(t)$ are known functions of time. Examples of parametric MI models include the Weibull, exponential, and Gompertz–Makeham survival analysis regression models. If covariates are time-independent, a Weibull-like parametric MI model would have $\alpha_{h0}(t, \gamma) = \alpha t^\rho$, where $\gamma = (\alpha, \rho)'$. Similarly, an exponential-like parametric MI model would have $\alpha_{h0}(t, \gamma) = \gamma$. The latter is also a Poisson-like MI model when each subject experiences only one event.

In addition to specifying the parametric form of the baseline intensity in a parametric MI model, one can assume that $N_{hi}(t)$ is a nonhomogeneous Poisson process. This means that, for each t , $dN_{hi}(t)$ has a Poisson distribution with the rate $\lambda_{hi}(t, \theta)$ and is independent of its history. Thus, $H(t^-)$ in (2) and (3) need not contain information on the process $N_{hi}(s)$ itself. The above Weibull and exponential specifications of baseline intensity can still be used along with the Poisson assumption to obtain parametric Poisson MI models for recurrent events. For the Weibull-like Poisson MI model for dealing with recurrent events, see Ref. [12].

Semiparametric Multiplicative Intensity Models

If, on the other hand, $\alpha_{h0}(t)$ is completely unknown, we can use the Andersen–Gill MI model, also known as a semiparametric MI model, without having to depend on unknown parameters.

The most well-known example of a semiparametric MI model is Cox's proportional hazards model for right-censored survival data. This model is obtained when only one type of a right-censored event occurs only once to each subject. Dropping the subscript h , we redefine the observed data as (X_i, δ_i) where X_i is either the event time or the censoring time for the i th subject, depending on which comes first, and δ_i is the status indicator, taking a value of 1 if X_i is the event time and 0 otherwise. We define $N_i(t) = I(X_i \leq t, \delta_i = 1)$, where $I(A)$ is 1 if A is true, and 0 otherwise. Similarly, the process $Y_i(t)$ can be redefined as

$$Y_i(t) = I(X_i \geq t) = I(\text{subject } i \text{ was alive and uncensored until just before } t)$$

Note that the nonhomogeneous Poisson assumption mentioned above for parametric MI models can still be used with a completely unspecified baseline intensity, thus obtaining a semiparametric Poisson MI model.^[12]

In general, the Poisson assumption (also known as memoryless property of the process) does not hold, since the re-occurrence of an event usually depends on previous occurrences. However, the Poisson assumption, both in the parametric and semiparametric set-up, has the advantage that (2) and (3) are interpretable as marginal probabilities and marginal means.

ESTIMATION AND HYPOTHESES TESTING

Given an MI model with an intensity function as in (6), the parameters $(\gamma', \beta')'$ have to be estimated in the parametric case. In the semiparametric case, the baseline cumulative intensity, $A_{h0}(t)$, and the vector of covariate effects, β , need to be estimated.

Before writing a likelihood for the model, we have to bear in mind that the independent censoring assumption is crucial in the case of right censoring, which terminates observation of the subject. Technically, a censoring mechanism is called “independent” if the intensity in (2) and (3) is not altered by knowing that the subject was not censored up until t^- and including this knowledge in the history $H(t^-)$. To write a “likelihood” for the model, one could use the heuristic argument that, given the history $H(t^-)$, $dN_{hi}(t)$ are independent Bernoulli random variables taking a value of 1 with probability $\lambda_{hi}(\theta, t)dt$. Hence, the joint likelihood of the data (excluding contributions from censoring times) is the product over time, event type and subjects of $[\lambda_{hi}(\theta, t)dt]^{dN_{hi}(t)}[1 - \lambda_{hi}(\theta, t)dt]^{1-dN_{hi}(t)}$.

$$L(\tau, \theta) = \prod_{0 \leq t \leq \tau} \prod_h \prod_i [\lambda_{hi}(\theta, t)dt]^{dN_{hi}(t)} \times [1 - \lambda_{hi}(\theta, t)dt]^{1-dN_{hi}(t)} \quad (9)$$

Manipulating (9) using product limit arguments, or treating $dN_{hi}(t)$ as a random variable following Poisson distribution with mean $\lambda_{hi}(\theta, t)dt$, given the history $H(t^-)$, one can rewrite the likelihood as

$$L(\tau, \theta) = \prod_h \prod_i \left[\prod_{0 \leq t \leq \tau} [\lambda_{hi}(\theta, t)dt]^{dN_{hi}(t)} \right] \times \exp \left(- \int_0^\tau \lambda_{hi}(\theta, t)dt \right) \quad (10)$$

These quantities are partial likelihoods, since the piece contributed by the censoring times is being ignored and it may carry some information about the parameters. If the independent censoring mechanism is also noninformative, (9) and (10) will be full likelihoods carrying all the information contained in the observed data about θ . Nevertheless, these partial likelihoods can be treated as full likelihoods with little loss of efficiency.^[3]

Parametric Multiplicative Intensity Models

To obtain score functions for the parametric MI model, we take the log of (10) with $\lambda_{hi}(\theta, t) = \alpha_{h0}(t, \gamma)Y_{hi}^*(t)e^{\beta'z_{hi}(t)}$. Note that the log of a continuous product over t becomes a continuous sum, and by differentiating this log partial likelihood with respect to (γ, β) , we get the system of score equations (see Ref. [7], p. 585)

$$\sum_h \sum_i \int_0^\tau \frac{(\partial/\partial \gamma_j) \alpha_{h0}(t, \gamma_j)}{\alpha_{h0}(t, \gamma_j)} dN_{hi}(t) - \sum_h \int_0^\tau \frac{\partial}{\partial \gamma_j} \alpha_{h0}(\gamma, t) S_h^{(0)}(t, \beta) dt = 0 \quad (11)$$

and

$$\sum_h \sum_i \int_0^\tau z_{hij}(t) dN_{hi}(t) - \sum_h \int_0^\tau \alpha_{h0}(\gamma, t) S_{hj}^{(1)}(t, \beta) dt = 0 \quad (12)$$

where $S_h^{(0)}(\beta, t) = \sum_{i=1}^n Y_{hi}(t) e^{\beta' z_{hi}(t)}$, and $S_{hj}^{(1)}(\beta, t) = \sum_i z_{hij} Y_{hi}(t) e^{\beta' z_{hi}(t)}$ is the first-order partial derivative of $S_h^{(0)}(\beta, t)$ with respect to β_j .

Solving Eqs. (11) and (12) with respect to (γ, β) , for example by the Newton–Raphson method, would render the maximum partial likelihood estimators of the parameters in the model, $\hat{\gamma}$ and $\hat{\beta}$. Since $dN_{hi}(t)$ is a step function with jumps of size 1, the integrals in the first terms of (11) and (12) are essentially discrete sums over ordered event times. For example, if $\{t_{hij}; j = 1, \dots, n_{hi}\}$ denotes ordered type h event times of the i th subject, then the first term of (11) becomes

$$\int_0^\tau \frac{\partial}{\partial \gamma} [\log \alpha_{h0}(t, \gamma)] dN_{hi}(t) = \sum_{j=1}^{n_{hi}} \frac{\partial}{\partial \gamma} [\log \alpha_{h0}(t_{hij}, \gamma)] \quad (13)$$

Similar arguments apply to the first term of (12).

The Fisher observed information can be partitioned according to the components of the parameter vector $(\gamma', \beta')'$ as follows:

$$I(\tau; \gamma, \beta) = \begin{pmatrix} I_{\gamma\gamma} & I_{\gamma\beta} \\ I_{\beta\gamma} & I_{\beta\beta} \end{pmatrix}$$

The quantities $I_{\gamma\gamma}$ and $I_{\gamma\beta}$ are the negatives of the derivative of the left-hand side of (11) for γ and β , respectively, and similarly, $I_{\beta\gamma}$ and $I_{\beta\beta}$ are the negatives of the derivatives of the left-hand side of (12) for γ and β , respectively. The inverse of this matrix evaluated at $(\hat{\gamma}', \hat{\beta}')'$ is a consistent estimator for the asymptotic covariance matrix of $(\hat{\gamma}', \hat{\beta}')'$.^[7,13]

The testing of hypotheses about $(\gamma', \beta')'$ can be based on the usual test statistics such as the likelihood ratio, Wald, and Rao's score. These are asymptotically χ^2 test statistics.^[13]

Semiparametric Multiplicative Intensity Models

For the semiparametric MI model, we again use (10) but without γ , i.e., $\alpha_{h0}(t, \gamma) = \alpha_{h0}(t)$. One can take the log-partial likelihood and differentiate it with respect to $\alpha_{h0}(t)$ and solve the score, explicitly, with respect to $\alpha_{h0}(t)dt$ to obtain

$$\hat{\alpha}_{h0}(t)dt = \sum_i dN_{hi}(t) / \sum_i Y_{hi}(t) e^{\beta' z_{hi}(t)} = d\hat{A}_{h0}(t, \beta) \quad (14)$$

By inserting this expression back into the partial likelihood (10), one essentially gets a partial likelihood involving β only,

$$L_\tau(\beta) = \prod_{0 \leq t \leq \tau} \prod_h \prod_i \left(\frac{e^{\beta' z_{hi}(t)}}{\sum_{i=1}^n Y_{hi}(t) e^{\beta' z_{hi}(t)}} \right)^{dN_{hi}(t)} \quad (15)$$

This is exactly the same as Cox's partial likelihood,^[1] and it has been shown^[3] that it can be treated as a full likelihood and used for inferences about β under some regularity conditions. The partial likelihood in (15) can also be thought of as the product over time, event-type, and subjects of the conditional probability of a type h event happening to the i th subject at time t given that a type h event has happened at that time to one of those at risk among the n subjects under study.^[1]

Taking the log of (15) and using the same arguments as above, we get

$$\log L_\tau(\beta) = \sum_h \sum_i \int_0^\tau [\beta' z_{hi}(t) - \log S_h^{(0)}(\beta, t)] dN_{hi}(t) \quad (16)$$

where $S_h^{(0)}(\beta, t)$ is defined as above. Therefore, components of the score vector [first-order partial derivatives of (16)] are

$$\begin{aligned} U_j(\beta, \tau) &= \frac{\partial}{\partial \beta_j} \log L_\tau(\beta) \\ &= \sum_h \sum_i \int_0^\tau \left[z_{hij}(t) - \frac{S_{hj}^{(1)}(\beta, t)}{S_h^{(0)}(\beta, t)} \right] dN_{hi}(t) \\ &= \sum_h \sum_i U_{hij}(\beta, \tau) \end{aligned} \quad (17)$$

where $S_{hj}^{(1)}(\beta, t)$ is the first-order partial derivative of $S_h^{(0)}(\beta, t)$ with respect to β_j . Thus, the j th component of the score vector can be written as the sum of contributions due to the h th event-type from the i th individual. Solving the system of equations, $U_j(\beta, \tau) = 0$ for $j = 1, \dots, p$ gives $\hat{\beta}$, the maximum partial likelihood estimator of β . The negative of the matrix of second-order partial derivatives of (16) is the observed Fisher information matrix $I(\hat{\beta}, \tau)$. The inverse of $I(\hat{\beta}, \tau)$ is a consistent estimator for the covariance matrix of $\hat{\beta}$ for large samples. To recognize the dependence of future events on past events, we can use the robust covariance of $(\hat{\beta})$, obtainable from *coxph* in *Splus* by using the *cluster(id)* argument, where *id* refers to the subject index.

Using (16), tests of hypotheses can be based on the usual likelihood ratio, Wald or score statistics, all of which have asymptotic χ^2 distributions. Both estimation and hypothesis testing for the semiparametric MI model are

implemented in the PROC PHREG and *coxph* functions of SAS and Splus, respectively.^[14]

Since statistical inferences for the parametric and semi-parametric MI models are based on partial likelihoods, tied event times from different subjects can be accommodated through the partial likelihoods using the techniques of Cox's proportional hazards model as discussed earlier.

Estimating the Cumulative Intensity Functions

Integrating $\hat{\alpha}_{h0}(t)dt$ and replacing β with its maximum partial likelihood estimator, we find that the Breslow estimator (also known as Tsiatis, Link, and Nelson–Aalen) for the cumulative baseline intensity function is given by

$$\hat{A}_{h0}(t, \hat{\beta}) = \int_0^t \frac{\sum_i dN_{hi}(s)}{\sum_{i=1}^n Y_{hi}(s)e^{\hat{\beta}'z_{hi}(s)}} \quad (18)$$

Using (14) or (18) and the definition of the cumulative intensity function, we can obtain an estimator for the cumulative intensity $\Lambda_{hi}(t, \beta)$ of a subject with covariate values $z_{hi}(t)$ as

$$\hat{\Lambda}_{hi}(t, \hat{\beta}) = \int_0^t Y_{hi}(s)e^{\hat{\beta}'z_{hi}(s)} d\hat{A}_{h0}(s, \hat{\beta}) \quad (19)$$

This expression reduces in practice to a discrete sum over the ordered event times of the subject, i.e.,

$$\hat{\Lambda}_{hi}(t, \hat{\beta}) = \sum_{t_{hij} \leq t} e^{\hat{\beta}'z_{hi}(t_{hij})} [\hat{A}_{h0}(t_{hij}, \hat{\beta}) - \hat{A}_{h0}(t_{hi(j-1)}, \hat{\beta})] \quad (20)$$

where $t_{hij}; j = 1, 2, \dots$ are the ordered type h event times for the i th subject.

The baseline cumulative intensity for a parametric MI model is estimated by replacing γ with its maximum partial likelihood estimator to get

$$\hat{\Lambda}(t, \hat{\gamma}) = \int_0^t \alpha_{h0}(s, \hat{\gamma}) ds \quad (21)$$

MODEL ASSESSMENT AND DIAGNOSTICS

To facilitate the discussion, let us assume there is only one type of recurrent event and drop the subscript h from the MI model. There are several assumptions underlying the MI model specification. Both parametric and semi-parametric MI models share the proportional intensity, the log-linearity, and the martingale assumptions, whereas in parametric MI models one is also concerned with the specific shape of the parametric cumulative baseline intensity,

$\Lambda_0(t, \theta)$. Most of the goodness-of-fit and diagnostic methods in the literature have been developed for semiparametric MI models, and especially for the Cox regression model. Therefore, our main focus in this section is on describing some of the techniques for semiparametric MI models, while briefly mentioning how they could be adapted to the parametric set-up.

The following residuals are useful for diagnosing MI regression models and assessing the model assumptions.

1. Martingale residuals for the i th subject,

$$\hat{M}_i(\tau) = N_i(\tau) - \hat{\Lambda}_i(\tau, \hat{\beta}) \quad (22)$$

where $\hat{\Lambda}_i(\tau, \hat{\beta}) = \int_0^\tau Y_i(t)e^{\hat{\beta}'z_i(t)} d\hat{A}_0(t, \hat{\beta})$ and $\hat{A}_0(t)$ is the Breslow estimator for the cumulative baseline intensity. Obviously, $\hat{\Lambda}_i(\tau, \hat{\beta})$ is essentially a discrete sum over event times since $\hat{A}_0(t, \hat{\beta})$ itself is available only at event times. From (4), this residual is usually interpreted as the observed number of events at time t minus the predicted number of events (from the MI model) at that time. Similarly, for parametric MI models,

$$\hat{M}_i(\tau) = N_i(\tau) - \hat{\Lambda}_i(\tau, \hat{\gamma}, \hat{\beta}) \quad (23)$$

where $\hat{\Lambda}_i(\tau, \hat{\gamma}, \hat{\beta}) = \int_0^\tau \alpha_0(t, \hat{\gamma}) Y_i(t) e^{\hat{\beta}'z_i(t)} dt$.

2. Schoenfeld residuals for the i th subject and j th covariate at time t ,

$$\hat{r}_{ij}(t) = z_{ij}(t) - \left[S_j^{(1)}(\hat{\beta}, t) / S^{(0)}(\hat{\beta}, t) \right] \quad (24)$$

which is exactly the integrand in (17) with estimated β .

3. Score residuals for the i th subject and j th covariate,

$$U_{ij}(\hat{\beta}, \tau) = \int_0^\tau \left[z_{ij}(t) - \frac{S_j^{(1)}(\hat{\beta}, t)}{S^{(0)}(\hat{\beta}, t)} \right] dN_i(t) \quad (25)$$

which is the contribution of subject i to the score function (17), evaluated at $\hat{\beta}$. These residuals are the sums of the Schoenfeld residuals of (24) over event times in $[0, \tau]$. Score residuals for β in the parametric MI model are slightly different and are given by

$$\int_0^\tau z_{ij} d \left[N_{hi}(t) - \hat{\Lambda}_i(t, \hat{\gamma}, \hat{\beta}) \right] \quad (26)$$

This expression is obtained by rearranging and estimating the left-hand side of (12).

Assessment of Influential Observations

We can measure the influence of the i th subject on the regression parameter estimates by computing

$\Delta^{(i)}\beta = \hat{\beta} - \hat{\beta}_{i-}$, where $\hat{\beta}$ is obtained by fitting the model using data from all subjects, and $\hat{\beta}_{i-}$ is the parameter estimator from a model not containing the i th subject. Plotting the elements of the vector $\Delta^{(i)}\beta$ against subject index would then reveal influential subjects (subjects with high leverage). Recomputing $\Delta^{(i)}\beta$ after removing each subject from the model can be computationally costly. Therefore, an often-used approximation to $\Delta^{(i)}\beta$ is the vector $I^{-1}(\hat{\beta}, \tau)(U_{i1}, \dots, U_{ip})'$, where $I^{-1}(\hat{\beta}, \tau)$ is the estimated covariance of $\hat{\beta}$ and U_{ij} are the score residuals (see Ref. [15] for a modified version of this approximation). These residuals are called *dfbetas* in SAS and Splus and can be saved for plotting purposes.

These methods are also applicable to parametric MI models with score residuals given in (26). See Ref. [15] for a discussion of the validity of these methods in the parametric case.

Assessment of the Log-Linearity Assumption

For time-independent covariates, the log-linearity assumption is that the log of the ratio of the intensity function to the baseline intensity function is linear in the covariates. That is, $\log \lambda_i(t, \theta)/\alpha_0(t, \gamma) = \beta'z_i$. This assumption would be violated if, for instance, the covariates enter the model in quadratic or other functional form. Also, certain covariates, say the first covariate z_1 , might need to be transformed before entering the model through the exponent in (6). These assumptions can be assessed by plotting the martingale residuals, $\hat{M}_i$, obtained from a model excluding the covariate z_1 , against the values of the covariate itself, z_{i1} . A smoothed-out version of such a scatter plot would give an indication of type of transformation required, as long as z_1 is not strongly correlated with the remaining covariates. This method and some modifications of it are suggested in Refs. [15,16] and implemented in the Splus function *cox.zph* (see Splus manual). In SAS, the martingale residual for a subject can be calculated by summing over all the rows corresponding to the subject, and can be saved using the RESMART option of the OUTPUT statement of PROC PHREG.

Proportional Intensity Assumption

The proportional intensity (PI) assumption is relevant when the covariates are not time dependent. In that case, the PI assumption is that the ratio of intensities for two subjects with distinct covariate values, say z_i and z_j , is time independent (constant), i.e., $\lambda_i(\beta, t)/\lambda_j(\beta, t) = e^{\beta'(z_i - z_j)}$. Note that the proportional intensity assumption becomes the proportional hazards (PH) assumption in the Cox model. This assumption is violated if β depends on time. Writing $\beta_j(t) = \beta + \theta g_j(t)$ for $j = 1, \dots, p$, where $g_j(t)$ are predictable processes, Grambsch and Therneau^[17] have shown that many tests appearing in the literature for checking the PI (or PH)

assumption are just tests for $H_0: \theta = 0$ with different choices of $g_j(t)$. These authors propose the use of a smoothed plot of rescaled Schoenfeld residuals against event times to reveal the functional form of the coefficients [i.e., the form of $g_j(t)$]. To do so, one would first extract the p -dimensional vector, $r(t_k)$, containing Schoenfeld residuals for all covariates of the only subject having an event at time t_k (if there are no ties). Then, we would form the scaled p -dimensional Schoenfeld residuals, $r^*(t_k) = [I^{-1}(\hat{\beta}, \tau)/d]r(t_k)$, where d is the total number of events in the sample and $\hat{\beta}$ is estimated under H_0 . If there are tied event times, then the Schoenfeld residuals in (24) use the average of covariate values, $z_{ij}(t_k)$, over all subjects having events at t_k . A smoothed scatter plot of the components of $r^*(t_k) + \hat{\beta}$ against t_k would then reveal the functional form of the corresponding coefficients, $\beta(t)$. The authors also provide χ^2 tests for checking the global hypothesis $\theta = 0$ and the hypotheses $\theta_j = 0$, regarding each parameter β_j for $j = 1, \dots, p$. Obviously, these tests are against alternatives with specific $g_j(t)$. Several $g_j(t)$, including identity, are available in the *cox.zph* function of Splus.

To use a simple graphic method of checking whether a given covariate with several levels (e.g., gender or age classes) complies with the PI assumption, one can stratify the MI model over the levels of the covariate and obtain estimated cumulative baseline intensities for each strata using (18). If the covariate in question complies with the PI assumption, then plots of the log of these estimated cumulative baseline intensities should give approximately parallel curves. Another useful method is to plot the estimated cumulative baseline intensities one against another (or each one against one stratum declared as a reference). Such plots are expected to be straight lines through the origin if the PI assumption is correct for the covariate. These plotting techniques can be used with parametric or semiparametric MI models.

Omnibus Goodness-of-Fit Methods

The MI model relies, globally, on an assumption that the cumulative intensity process is the predictable process that makes (4) a martingale. If this process is a martingale, then the model is correct, regardless of the form of the intensity function, $\lambda_i(\beta, t)$. Tests and diagnostic plots based on this assumption can be called “omnibus” in the sense that we examine all the assumptions including PI and functional forms of the covariates by checking only the martingale assumption.

For instance, if the martingale assumption is correct, then taking the expected value of both sides of (4), as mentioned above, will imply that the expected number of events up to time t for a subject is $\Lambda_i(t, \theta)$. Thus, the estimated version of this cumulative intensity summed over all subjects should approximate the observed number of events in the sample up to time t . If the martingale assumption is correct, then a plot of $\sum_i \Lambda_i(t, \theta)$ against the cumulative observed number of events in the sample up to t will

give a straight line through the origin with a unit slope (see Refs. [7,18]).

Recently, Jones and Harrington^[19] proposed tests for this martingale assumption by exploiting the fact that, if the $M_i(t)$ processes defined in (4) were martingales, then their estimated versions at successive event times would be approximately martingales and hence would have uncorrelated increments with mean 0. They developed two statistics, Q'' and Q_{cor} , for testing the mean 0 and uncorrelated increments properties, respectively. These tests are asymptotically χ^2 and are useful for checking the global fit of the model.

Checking Parametric Baseline Intensity Form

To check the validity of a presumed baseline intensity function for parametric MI models, one can plot the Breslow estimate of the semiparametric cumulative baseline intensity in (18) against (21) obtained from fitting the presumed parametric model. If the assumed parametric baseline is reasonable, then this plot should give a straight line through the origin.

Alternatively, the log of the Breslow estimator can be plotted against time or a transformation of time for specific parametric baseline shapes, thus bypassing the need to fit a parametric model. For example, for a presumed Weibull-like baseline intensity with $\Lambda_0(t, \gamma) = \alpha t^\rho$, the plot of $\log \Lambda_0(t, \hat{\beta})$ against $\log t$ would give approximately a straight line with intercept $\log \alpha$ and slope ρ .

Nested parametric MI models can also be identified through the usual -2 log-likelihood difference in the two models. For example, to check whether an exponential-like parametric MI model is better than a Weibull-like model, one can use the usual G^2 , which would follow a χ^2 distribution with 1 degree of freedom.

Multiplicative Intensity Models with Frailty

In practice, data exhibit more heterogeneity than is usually explainable by the covariates in the model. This heterogeneity can be due to unobserved characteristics of the individuals in the study. One way to tackle this problem is to assume that each subject belongs to a family (a cluster) and each family is characterized by a random unobserved frailty, X_l ; $l = 1, 2, \dots$. The family can be made up of the subject itself, in which case the subject ID is used to index the frailty. Usually, the x_l are assumed to be from a gamma distribution with mean 1 and variance $1/\nu$ and they enter the model through (6) in a multiplicative way, i.e., $\lambda_{hi}(t, \theta) = \hat{x}_l \alpha_{h0}(t, \gamma) \gamma_{hi}(t) e^{\beta' z_{hi}(t)}$. As $\nu \rightarrow \infty$, the variance goes to 0 and the model becomes a frailty-less MI model.

The estimation procedure uses the EM algorithm (see Ref. [7]), whose E-step replaces the unobserved realizations of the X_l with their expected values given the observed data, $\hat{x}_l = E[X_l | N, Y, Z]$, assuming that censoring

is noninformative about $\alpha_{h0}(t, \gamma)$ and β , given the realizations of the frailties. Then the log-partial likelihood in (16) is maximized with respect to the unknown parameters, including ν , in the M-step of the EM algorithm using intensities $\lambda_{hi}(t, \theta) = \hat{x}_l \alpha_{h0}(t, \gamma) \gamma_{hi}(t) e^{\beta' z_{hi}(t)}$. The partial likelihood so obtained is actually equivalent to the one obtained by integrating frailties out of the partial likelihood for the complete data, i.e., both observed and unobserved data (N, Y, Z, X). Therefore, the resulting likelihood is usually called a “marginal partial likelihood,” and is used as a partial likelihood for testing hypotheses about θ and ν . Multiplicative intensity models with gamma frailties can be fitted using the *coxph* function in Spls by adding the term *frailty(family, dist=“Gamma”)* to the model specification, where family is a variable indexing the cluster (family), which could be equal to the subject ID. Recently, Therneau, Grambsch, and Pankratz^[20] provided an algorithm for fitting MI frailty models using a penalized likelihood approach.

CONCLUSIONS

This entry is an overview of multiplicative intensity models. We presented parametric and semiparametric MI models, along with established strategies for estimating and testing the model parameters. We then discussed a number of related technical issues for applications. These include the use of frailties for modeling dependence among recurrent events of the same subject. Other well established methodologies for analyzing recurrent event data are those of Wei, Lin, and Weissfeld (WLW) and Printice, William, and Peterson (PWP). For a discussion of these methods, see Ref. [21]. Also, Yau and McGilchrist^[22] proposed a strategy for completely bypassing the MI models. Another issue of great importance in using MI models is the presence of dependent censoring. For example, under dependent censoring, the interpretation of the intensity function as an instantaneous net hazard rate is not possible using Cox’s proportional hazards model.^[10] Alternative MI models for dealing with dependent censoring in the recurrent event analysis are proposed in Ref. [23]. However, we note that most of these techniques are based on an asymptotic theory, requiring large samples. A comprehensive simulation study that examines finite sample performance of the inference procedures would be of great importance in practice.

Abstract

Multiplicity, loosely defined, refers to multiple inferences that are made in a simultaneous context. Much attention has been given to multiplicity issues in clinical trials over the past few decades, culminating in recent guidance documents from the European Medicines Agency's Committee for Human Medical Products and the US Food and Drug Administration. As discussed in these regulatory documents, multiplicity arises in almost any clinical trial: Potential sources include comparison of several treatment or dose groups, multiple endpoints, multiple time points, interim analyses, multiple tests of the same hypothesis (e.g., parametric and nonparametric), variable and model selection, and subgroup analysis. In this review article, some questions and problems related to multiplicity are highlighted, and some of the more recent solutions involving multiple comparisons procedures are discussed as they appear in the recent guidance documents.

Keywords: Bayesian methods; Dose–response function; False discovery rate; Family-wise error rate; Primary endpoints; Replicability; Safety endpoints; Secondary endpoints; Subgroup analysis.

INTRODUCTION

Multiplicity, loosely defined, refers to multiple inferences that are made in a simultaneous context. Much attention has been given to multiplicity issues in clinical trials over the past few decades,^[1–7] culminating in recent guidance documents from the European Medicines Agency's Committee for Human Medical Products (CHMP)^[8] and the US Food and Drug Administration (FDA).^[9] As discussed in these regulatory documents, multiplicity arises in almost any clinical trial: Potential sources include comparison of several treatment or dose groups, multiple endpoints, multiple time points, interim analyses, multiple tests of the same hypothesis (e.g., parametric and nonparametric), variable and model selection, and subgroup analysis. In this review article, some questions and problems related to multiplicity are highlighted, and some of the more recent solutions involving multiple comparisons procedures (MCPs) are discussed as they appear in the recent guidance documents.

Statistical practices of the pharmaceutical industry are largely driven by expectations of the regulatory agencies. The CHMP guideline states^[8]:

In clinical studies it is often necessary to answer more than one question about the efficacy (or safety) of the experimental treatment in a specific disease, because the success of a drug development programme may depend on a

positive answer to more than a single question. It is well known that the likelihood of a positive chance finding increases with the number of questions posed, if no actions are taken to protect against the inflation of false positive findings from multiple statistical tests.

The FDA guideline states similarly^[9]

Most clinical trials performed in drug development contain multiple endpoints to assess the effects of the drug and to document the ability of the drug to favorably affect one or more disease characteristics. As the number of endpoints analyzed in a single trial increases, the likelihood of making false conclusions about a drug's effects with respect to one or more of those endpoints becomes a concern if there is not appropriate adjustment for multiplicity.

While these documents acknowledge that multiplicity adjustment is sometimes unnecessary, they also suggest strongly that such non-adjustment be carefully justified. As a result, simple adjustment procedures that control the family-wise error rate (FWER) are routinely incorporated in the study protocols of pharmaceutical companies. There are many FWER-controlling procedures, and the simple Bonferroni method can be pointed out as a useful (although somewhat conservative) standard. This method simply requires that if there are k inferences in a family,

then all inferences should be performed at the α/k significance level rather than at the α level. The result is that the FWER, or probability of declaring one or more false positives, is no more than α .

THE PROBLEM: REPLICATION

The scientific concern surrounding multiplicity is whether the reported effects from the clinical trial will replicate in the general patient population. Lack of replication can occur in three ways: (i) the drug is ineffective in the general patient population, despite being “efficacious” in the clinical trial study; (ii) the drug has an effect in the opposite direction in the patient population as it had in the clinical study; (iii) the drug’s effect size in the patient population is substantially lower than it is in the clinical study.

Specific explanations of these problems follow:

- Errors of declaring effects when none exist
The classical characterization is in terms of the “1 in 20” significance criterion: In 20 tests of hypotheses, all of which are (unknown to the trialist) truly null, one false positive result is expected. Thus, repeated testing can increase the likelihood of false positives.
- Errors of declaring effects in the “wrong direction”
One might not believe point-zero null hypotheses can truly exist, in which case the “1 in 20” explanation has little impact. Another point of view, similar to the testing point of view, is that it is likely that directions of the claims can be erroneous when multiple tests are used without multiplicity adjustment. For example, if a test of a two-sided hypothesis is performed at the .05 level, then there is (at most) a .025 probability that the test will be declared significant, but in the wrong direction. When multiple tests are performed, this probability accumulates, so that if 40 tests are performed, one directional error (in a worst case) may be expected. Even when multiplicity adjustments are performed, some do not control the probability of erroneous sign declaration.^[10]
- Errors of declaring inflated effect sizes
A third characterization of the multiplicity problem is in terms of selection effects. In this scenario, directional errors need not be postulated. In fact, it can be believed with a priori certainty that all effects are in their expected directions. Nevertheless, when a single, “most significant” comparison is isolated from this collection, it can only be presumed that the effect size is biased upward because of selection effects.^[11]

In all these three characterizations, there is a concern that the presentation of the scientific findings from the study may be exaggerated. By adopting a more conservative stance, MCPs aim to avoid such replication errors.

Is multiplicity really a cause for concern? Does the multiple comparisons problem truly cause exaggerated claims that do not replicate in the follow-up studies? The answer is “yes”; several such documented instances are reported.^[12–14] It is not at all uncommon in pharmaceutical research to find that effect sizes either do not replicate or replicate at a much lower level than was previously expected. Such failure to replicate has similarly been a recent concern in virtually all of science.^[15]

While problems of lack of replication are often attributed to poor designs and data collection procedures,^[12] it is as plausible that they result from selection effects related to the multiplicity problem. In many cases, such effects can be subtle. For example, a clinical efficacy measure might be taken one month after the administration of the drug. The efficacy can be determined by (i) using the raw measure, (ii) using the percentage change from baseline, (iii) using the actual change from baseline, or (iv) using the baseline covariate-adjusted raw measure. If an aggressive strategy where the “best” (most significant) measure is chosen, then the reported effect size measure will be clearly inflated because the maximal statistic capitalizes (unfairly) on random variations in the data. In such a case, it is not surprising that the follow-up studies produce less stellar results; this phenomenon is simply an example of regression to the mean.

SKEPTICISM: A GUIDING PRINCIPLE FOR MULTIPLICITY MANAGEMENT IN CLINICAL TRIALS

Pharmaceutical companies and research institutions that conduct clinical trials (hereafter, simply “sponsors”) are naturally loath to adopt conservative strategies for the analysis of efficacy data; after all, if the data fail to clear the more conservative hurdle, then drug approval might be delayed, at great cost to the company. On the other hand, reviewers from regulatory agencies or journals, and members of monitoring committees (hereafter, simply “reviewers”) have a right and an obligation to be skeptical, as motives of a sponsor can sometimes override scientific objectivity. Thus, it is sensible that reviewers should request a multiplicity correction, one that is within reasonable limits of skepticism that apply to the case at hand. Consider the following simple example. Suppose a sponsor decides to claim efficacy by establishing a significant treatment effect in any one of the various patient subgroups. The reviewer may adopt the skeptical position that the drug might not work at all, in any subgroup, in which case a multiplicity correction that considers the given set of subgroups (which would determine the “family” and the Bonferroni k) is appropriate. Examples showing how careless, non-skeptical analysis of subgroups can lead to type I errors in clinical trials are reported in the literature.^[13,14]

It is not always obvious what the appropriate “family” should be, but skepticism can help to resolve some of the difficulties. As another example, suppose several clinical compounds are to be evaluated against a standard. The experiment can be performed in two ways: (i) all compounds are compared with a standard at a given research center, or (ii) compound i is compared against the standard at research center i . In either case, the goal is to discover which compounds beat the standard.

Duncan^[16] suggests that multiplicity adjustment is not necessary in case (ii) since there are separate experiments. However, the guiding principle of skepticism dispels such thinking. A skeptical position is that few to none of the compounds are better, regardless of whether the experiments are concurrent or separate. Either way, there is an inflated probability of one or more type I errors over the set of tests when the skeptical position is, in reality, correct. Assuming an interest in protecting FWER for the collection of compounds tested, the a priori need for multiplicity correction is identical for cases (i) and (ii).

Cook and Farewell^[17] argue that no adjustment for multiplicity is necessary if a few, preselected endpoints in a clinical trial are to be “marginally” interpreted. Such a strategy may not satisfy the skeptical reviewer. Consider the case of a drug that is tested against an active competitor, and that significance with respect to each of a collection of endpoints is tested. A skeptical point of view is that the two formulations are a priori equivalent. In such a case, isolation of the “most significant” endpoint, and claiming improved efficacy on that measure, is sure to overstate the evidence. A skeptical reviewer has every right to demand a stronger standard of evidence than the unadjusted comparisons that the sponsor might offer.

SKEPTICISM AND BAYESIAN STATISTICS

The skeptical point of view naturally falls within the paradigm of Bayesian statistics, as “skepticism” is simply a prior opinion. Being skeptical can be instantiated by choosing a skeptical Bayesian prior distribution. Acceptance of multiple comparisons methods is largely determined by a person’s degree of skepticism rather than their philosophical orientation (Bayesian or frequentist). Because it is skepticism that motivates a concern for multiple comparisons and selection effects, it can be said that a lack of concern for multiple comparisons reflects a lack of skepticism.

Another FDA guideline that concerns the use of Bayesian statistics in medical device clinical trials^[18] echoes these sentiments, at least indirectly, with regard to (skeptical) Bayesian analyses:

While the Bayesian approach is often favorable to the investigator with good prior information, the approach can be more conservative than a frequentist approach.

Bayesian methods can be more conservative when skeptical priors are used. Spiegelhalter et al.^[19] define a “skeptical prior” to be one where the prior distribution of the effect size is centered at 0, while an “aggressive prior” places the prior mean of the effect size at a positive value, with small probability to the left of zero, suggesting an a priori belief in a treatment effect. This notion of a skeptical prior is also used to justify the ethics of performing clinical trials^[20]; after all, if there is no doubt about efficacy, then there is no ethical reason for conducting a placebo-controlled trial.

Spiegelhalter’s “skeptical” prior is unrealistic because it suggests that the effect is as likely to be positive as

Fig. 1 Skeptical and aggressive priors for treatment difference: (a) semiskeptical; (b) aggressive; (c) skeptical; (d) combines elements of skeptical and aggressive priors

negative. However, the “aggressive” prior is also unrealistic as it contradicts the ethics of running a clinical trial. More flexible priors are needed to model skepticism.

Gönen et al.^[21] estimate that, in oncology trials, a prior that places approximately 50% probability on the null hypothesis has empirical support; Berger and Sellke^[22] discuss the use of such mixture priors that place a positive probability on an effect size of zero. Such a prior is flexible enough to allow that there is (i) residual doubt concerning the existence of an effect and (ii) prior evidence of a positive effect (otherwise, why would an expensive trial be entertained?). Figure 1 displays various prior distributions for effect sizes, including the skeptical and aggressive priors of Spiegelhalter et al., and the corresponding priors that allow a greater degree of skepticism through the use of point masses.

Skepticism also motivates the use of Bayesian hierarchical models that employ shrinkage to downweight extreme, selected effects.^[23] In conjunction with skeptical priors, shrinkage estimates provide excellent solutions to the problem-inflated estimates due to selection effects. Extensive literature exists that discusses these priors, mathematical details surrounding the methodology for clinical trials, and the software used for its implementation.^[21,24,25]

THE CONTROVERSIES

There are several controversial aspects about the use of MCPs in clinical trials. We detail a few of the common ones here.

Controversy 1: In Multiple-Dose Studies, Why Is There a Penalty for “Doing a Better Job”?

Compare, for instance, the following: (i) a placebo-controlled trial with a single active treatment arm and (ii) a placebo-controlled trial with two active treatment arms at different dose levels. Surely the design (ii) is scientifically more informative, so why must the investigator pay a multiplicity penalty?

The reason is that having two doses instead of one increases the likelihood of declaring a significant effect when there is none, if not adjusted properly. The need for MCPs in multiple-dose studies can thus be justified, again, from the skeptical viewpoint. If the goal of the study is to take the “most significant” contrast forward to the approval process, then the evidence will be clearly overstated. A skeptical reviewer may take the point of view that the estimates should be appropriately “shrunk,” which typically requires Bayesian modeling with an appropriately skeptical prior, or that an MCP be adopted. In either case, the hurdle to establish efficacy is higher.

Consider now the case where many doses, say 20, are used. If the goal is to make individual statements about all of the doses, the multiplicity problem is even more evident

than in the previous case with two doses. It is likely that that sample dose–response function will suggest various kinds of non-monotonicities, purely as a result of chance variation in the data. This extreme case suggests that, with increasing doses, the goal should not be multiple comparisons among the doses, but should rather be dose–response curve estimation using regression methods. However, the multiplicity problem still persists because of the uncertainty about the true dose–response model and the inherent need for model selection.^[26]

Controversy 2: Why Not Adjust for Multiplicity of All Tests Performed in the Entire Trial? or in Your Lifetime for That Matter?

This is a common criticism of MCPs. If one is concerned about ever making a type I error, then we may as well give up all hope of making any claim whatsoever, because, as the question suggests, we would have to adjust every test in our lifetime, and the Bonferroni k (or size of the family) would be virtually infinite.

The question reflects a genuine concern and thoughtfulness about the multiplicity issue, but also reflects an avoidance strategy. Most people would agree that multiplicity needs to be managed at some level—it is simply bad science to indiscriminately “data snoop,” with the hope that comparison-wise significance levels provide an appropriate type I error screen.

The “no multiplicity adjustments are necessary” message that has been presented by some statisticians^[27–29] is a potentially dangerous and irresponsible message. If statisticians give the “no adjustment needed” message to our scientist colleagues, they will acquire the idea that it is not an issue, and that “anything goes.” The negative consequences of the “no adjustments necessary” message are that spurious associations are published, results fail to replicate, and inappropriate therapies are recommended.

Multiplicity cannot be controlled, but it can be managed. All competent statisticians will agree that there are places where multiplicity is a concern. But statisticians differ as to where exactly to draw the line, between places where multiplicity is a concern and places where it is not a concern. Statisticians also differ over whether and how to select prior distributions. It turns out that there is a surprising relationship between this issue and the multiplicity issue.^[24,25]

Controversy 3: Suppose That We Wish to Use Multiplicity Adjustment. How Do We Choose “Families” of Tests?

While every clinical trial is unique, Fig. 2 provides some suggested guidance concerning family selection in a “generic” trial. In most trials, there are various tests that are performed; these can be loosely divided into families of “efficacy,” “safety,” and “exploratory” tests. The

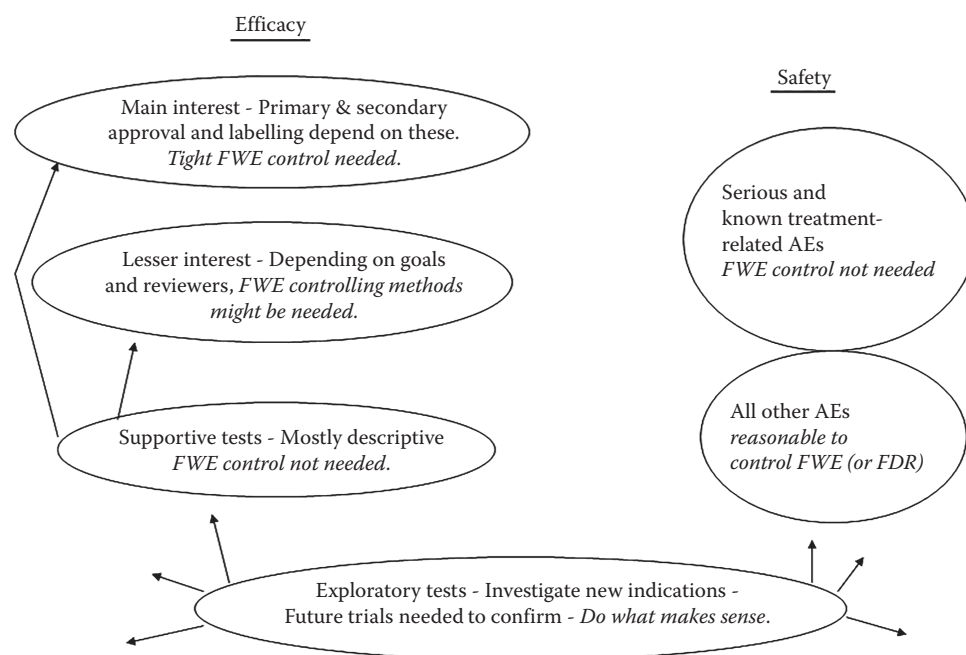

Fig. 2 A categorization of families in clinical trials, with recommended degrees of error rate control within each family

“efficacy” family is further subdivided into “primary efficacy,” “secondary efficacy,” and “supportive” tests. In the primary efficacy family, there are primary endpoint(s) and main secondary endpoints, for which regulatory approval is desired. In this family, the evidence for any claimed significances should be convincing enough to satisfy a skeptical reviewer, and therefore, it is desirable to have strong family-wise control for this set. Moving down the “efficacy side” to the “lesser interest tests,” for which an example may be multiple time point analyses for onset of therapeutic benefit, it is not recommended that this group be included in the primary (top level) family. Nevertheless, some claims may be desired for this set as well; if such tests are placed within a family and multiplicity adjustment is performed over such a family, then it goes without saying that any resulting significances are on stronger ground than if no multiplicity adjustment was performed at all. Finally, the supportive tests (e.g., alternative statistical analyses, alternative surrogate measures) are simply meant to support the primary findings. The intent of these tests is never to claim significance; that is, there is no “rescuing” of a poor primary result here. Rather, these tests can only cast doubt on significances obtained from the primary analyses, and therefore, no type I error adjustment is needed. The categorization of efficacy analyses in Fig. 2 roughly mirrors the rationale clinical endpoint classification by FDA^[9] into primary, secondary, and exploratory endpoints. This classification comes together with the recommendation to control the FWER across all primary and secondary endpoint analyses as they support drug approval and product label, respectively.

On the safety side, the adverse events (AEs) can be divided into two “families,” one including AEs that are

serious and with known treatment-related effects, and the other including the remainder. Type II errors are of much greater concern in the first group. Therefore, no multiplicity adjustment is needed. In fact, even simple trends may be reasonable “flags” here, even if the result is statistically insignificant without multiplicity adjustment.

Alternatively, one may formulate the set of hypotheses regarding serious AEs as multiple equivalence tests in which case it also makes sense to control FWER for that family.^[30]

However, for the remaining set of AEs, there is clearly a need to recognize the multiplicity problem, as one may expect, a priori, that there will be spurious significances in this set when no multiplicity adjustment is adopted. Recognizing the seriousness of type II errors for this case, a reasonable strategy is to present multiplicity-adjusted results side by side with unadjusted results. Reviewers may then make decisions that properly acknowledge the multiplicity problem.

False discovery rate (FDR) controlling methods^[31] have gained enormously in popularity since they offer more power, at the expense of increased type I error frequency. Use of FDR may be helpful here for the collection of secondary AEs.^[32]

At the bottom of the list is the family of exploratory tests. This family is placed in between the safety and efficacy sets, as both types of tests are included. The family may include, as an example, genetic subgroup analyses determined by combinations of single-nucleotide polymorphism markers, and thus may be huge, with the family size k in the thousands. Approval of product is not intended here; rather, the tests are indicative of needs for future study. Standard multiplicity adjustment here seems unreasonable, as power

will be very low; on the other hand, spurious p values less than .0001 are common with so many tests. The cost of type I errors is high here, whether on the safety side or on the efficacy side. On the safety side, there are costs of frivolous lawsuits and lost marketing opportunity costs; on the efficacy side, there are costs of spending resources on ineffective products. FDR controlling methods are useful here as well, and there is currently an enormous stream of literature on the use of such methods for large, exploratory MCPs.

While Fig. 2 provides a high-level guidance on how to select suitable families of hypotheses and error rates, more detailed suggestions still have to be established in many areas of practical concerns, as the boundary between confirmatory inference and exploratory analysis is not always clear. One example is the postmarketing investigation of a drug, where multiple trials may be conducted to understand the effect of alternative outcome measures, in additional subgroups, etc. These trials aim either for label extensions or for publications to better market the new product. One may argue that instead of running separate trials, it is more efficient and ethical to have a single trial (if feasible). The question is whether the type I error rate should be controlled across all endpoints, subgroups, etc., which otherwise would have been addressed in separate studies, each performed at level α . In such situations, however, the boundary versus an exploratory study can be blurred, as multiple study objectives may be prespecified in the study protocol, and one might be tempted to publish or submit only the significant results at an unadjusted level.^[33]

CLOSED TESTING METHODS AND APPLICATIONS TO CLINICAL TRIALS

Despite the fact that it has been more than 40 years since the initial development of the closed testing methodology,^[34] clinical trial designs that utilize closed testing have

only recently become more popular. The reason for this popularity is the incredible flexibility of the closed testing paradigm and its specific applicability to clinical trials^[9]: within its boundaries are found fixed sequence (or a priori ordered) methods, gatekeeping methods, dose–response methods, weighted methods, and methods that consider multiple endpoints and multiple doses simultaneously. An additional reason for the popularity is a guarantee of FWER control. No matter how complex a statistical analysis plan, FWER can be assured, provided that the plan is a special case of a closed testing procedure. Finally, closed testing procedures often are more powerful than classic MCPs, such as the Bonferroni, Tukey, and Dunnett procedures.

Closed testing is easy to describe: First, form all intersections of the elementary hypothesis H_1 , H_2 , etc., and then test all intersections using unadjusted tests. An elementary hypothesis H_i is then declared significant if all intersections that include the elementary hypothesis as a component of the intersection are significant. There is considerable flexibility in the choice of tests for the intersection hypotheses, leading to the wide variety of procedures that fall within the closed testing umbrella.

FIXED SEQUENCE OF OR A PRIORI ORDERED CLINICAL OBJECTIVES

A popular method in clinical trials, the fixed sequence procedure^[9] allows the analyst to impose an a priori order on the hypotheses such as H_1 , H_2 , and H_3 , presuming a natural ordering such as primary and secondary objectives in a clinical trial.^[35] This procedure and the closure method are illustrated in Fig. 3.

Notice that all intersection hypotheses are shown in Fig. 3, above the bottom row where the elementary hypotheses are shown. The flexibility of closed testing allows

Fig. 3 The fixed sequence procedure as a closed testing procedure

many possible tests for the intersections; in Fig. 3, the tests that give rise to the fixed sequence procedure are shown. Following closed testing, H_1 is rejected if $H_1, H_{12}, H_{13},$ and H_{123} are all rejected using the chosen tests for the intersection hypotheses. If all are tested using the p -value for H_1 only as shown, then one rejects H_1 simply if $p_1 \leq .05$. The remaining hypotheses are rejected using the same procedure; the choice of tests for the intersections thus require that H_2 is rejected if $p_1 \leq .05$ and $p_2 \leq .05$; and that H_3 is rejected if H_2 is rejected if $p_1 \leq .05, p_2 \leq .05,$ and $p_3 \leq .05$. Thus, the fixed sequence procedure is one in which testing continues in the a priori order, stopping as soon as a “fail to reject” decision is reached.

GATEKEEPING PROCEDURES FOR PRIMARY AND SECONDARY ENDPOINTS

Like the fixed sequence method, gatekeeping procedures are also commonly used for clinical trials with ordered objectives.^[9] The prototypical application considers a single primary objective and several, equally weighted secondary objectives. The method allows claims for secondary endpoints once the primary objective of the trial has been met. While other means for declaring secondary variables exist, the gatekeeping strategy can be considered a “gold standard” for placing secondary indications in the label, as full FWER control is assured across the entire collection.

Specifically, let H_1 denote the hypothesis that there is no effect in the primary measure, and let $H_2, H_3, \dots, H_k$ denote a set of secondary endpoints. To make claims about the hypotheses $H_1, H_2, \dots, H_k$ (the primary and secondary endpoints) with full FWER control, the gatekeeping procedure is as follows^[41]:

STEP 1

Test H_1 at (unadjusted) significance level α . If significant, proceed. Otherwise stop.

STEP 2

Test $H_2, H_3, \dots, H_k$ using a closed testing procedure specific to these $k-1$ secondary endpoints. Specifically, if the Bonferroni procedure is used, then the critical point is $\alpha/(k-1)$. Declare all secondary endpoints that meet the more stringent criterion to be statistically significant.

At Step 2, there are a variety of possible tests that could be used instead of the Bonferroni method. Reasonable possibilities include closed testing with the Simes,^[36] O’Brien,^[37] or min- P test.^[38] One can show that gatekeeping procedures are a special case of closed testing,^[39] which often lead to sequentially rejective testing procedures.^[40]

That is, shortcuts can be derived such that the closed hypotheses set is reduced to testing k hypotheses in a data-driven sequence. Because gatekeeping procedures mostly rely on the closed testing principle, they allow mapping of the difference in importance as well as the relationship between the various research questions onto an adequate multiple testing procedure. As a consequence, there has been an explosion of extensions of basic gatekeeping procedure described above that allow multiple doses, multiple endpoints, and weighted hypotheses.^[9]

Consider as an example a Bonferroni-based gatekeeping procedure for testing two primary hypotheses (H_1 and H_2) and, if at least one of them is significant, two secondary hypotheses (H_3 and H_4).^[41] In the simplest case, the two primary hypotheses are initially assigned the local level $\alpha/2$ each, whereas the secondary hypotheses are assigned the local level 0. If one of the primary hypotheses is rejected (i.e., either H_1 or H_2), the local level $\alpha/2$ is split into half and passed on to the secondary hypotheses. Testing continues with the remaining, nonrejected hypotheses at the updated local significance levels until no further hypothesis can be rejected. Further extension to gatekeeping procedures addressing complex questions is available.^[42–46]

In the meantime, the development of gatekeeping procedures has become rather technical, and the underlying test strategies have often become difficult to communicate. Graphical approaches to sequentially rejective multiple testing procedures have been proposed instead and recommended in the recent FDA guideline,^[9] which allow better communication with clinical teams.^[47,48] Using a graphical approach, null hypotheses are represented by a set of vertices with associated weights representing local significance levels. The weight associated with a directed edge between any two vertices indicates the fraction of the (local) significance level at the initial vertex (tail) that is added to the significance level at the terminal vertex (head), if the hypothesis at the tail is rejected. See Fig. 4 for an example, which visualizes the gatekeeping procedure discussed previously.^[41]

While the technical development of gatekeeping procedures is still evolving, attention needs to be given to potential “illogical problems”^[49] and the need to ensure “consistency”^[50] when selecting a suitable testing strategy.

Fig. 4 Graphical illustration of a gatekeeping procedure^[41] with four hypotheses

CONCLUSION

Spurred by the latest regulatory guidelines,^[8,9] this article provided a current look at the issues, controversies, and methodologies that concern multiple comparisons in clinical trials. An insight into the need for multiple comparisons from the skeptical point of view, a point of view that also provides guidance for analysis strategies, was given. Some MCPs are currently popular; gatekeeping procedures were described in detail. Finally, the use of Bayesian methods and FDR controlling methods, both of which are gaining popularity for addressing certain aspects of multiplicity in clinical trials, was suggested. A glaring omission in this article is group sequential and adaptive designs; we instead refer to the literature for the available statistical methods and regulatory guidance.^[51–53]

Abstract

In recent years, multiregional clinical trials (MRCTs) that conduct clinical trials simultaneously in Asia-Pacific region, Europe and the United States have become very popular for global pharmaceutical development. The purpose of MRCTs is to shorten the time for pharmaceutical development and regulatory development, submission, and approval around the world. In practice, however, clinical results observed from some regions (subpopulation) may not be consistent with the results from other regions and/or all regions combined (entire population). It is a concern for regulatory review and approval of the clinical results of the region that is inconsistent with all other regions. The inconsistency observed may be due to ethnic differences in different regions and/or similar but different regulatory requirements, study protocol/designs, study endpoints, or time points of assessment, or by random chance due to small sample size for the region. In this article, critical issues that are commonly encountered in an MRCT are discussed. Several statistical tests for consistency (similarity) between clinical results observed from a specific subpopulation and the entire population are presented. As most published articles discussed consistency evaluation for superiority situations, we discussed consistency evaluation for non-inferiority situation in this article through a simulated example concerning consistency in some countries.

Keywords: Assurance probability; Consistency index; Non-inferiority; Sensitivity index; Similarity; Superiority; Test for consistency.

INTRODUCTION

In recent years, multi-regional (or multi-national) multi-center clinical trials have become very popular in global pharmaceutical and/or clinical development. The main purpose of a multiregional clinical trial (MRCT) is not only to assess the efficacy of the test treatment over all regions in the trial but also to bridge the overall effect of the test treatment to each of the region in the trial. Most importantly, an MRCT is to shorten the time for pharmaceutical development and regulatory development, submission, and approval around the world. Although MRCTs provide the opportunity to fully utilize clinical data from all regions to support regional (local) registration, some critical issues such as regional differences (e.g., culture and medical practice/perception) and possible treatment-by-region

interaction that may have an impact on the validity of the multiregional trials inevitably occur.

In multiregional trials for global pharmaceutical/clinical development, one of the commonly encountered critical issues is that clinical results observed from some regions (e.g., Asia-Pacific region) are inconsistent with clinical results from other regions (e.g., the European Community) or global results (i.e., all regions combined). The inconsistency in clinical results between different regions (e.g., Asia-Pacific region and the European Community and/or the United States) could be due to the difference in ethnic factor. In this case, the dose or dose regimen may require adjustment or a bridging study may be required before the data can be pooled for an overall combined assessment of the treatment effect. As a result, evaluation of consistency between specific regions (subpopulation) and all regions

combined (global population) is necessarily conducted before regional registration (e.g., Japan and China). It should be noted that different regions may have different requirements regarding sample sizes at specific regions in order to fulfill with regulatory requirement for registration.^[1]

In practice, consistency between clinical results observed from a subpopulation (specific region such as Japan or China) and the entire population (all regions combined) is often interpreted as similarity and/or equivalence between the two populations in terms of treatment effect (i.e., safety and/or efficacy). Along this line, several statistical methods including test for consistency,^[2] assessment of consistency index,^[3] evaluation of sensitivity index,^[4] achievement of reproducibility and/or generalizability,^[5] Bayesian approach,^[6,7] and the Japanese approach for evaluation of assurance probability^[1] have been proposed in the literature.^[8] The purpose of this article is to provide an overview of these methods.

In the next section, some critical issues that are commonly encountered in multiregional, multicenter trials are discussed. Several statistical methods for testing consistency or similarity/equivalence in clinical results observed from a subpopulation compared to that of the entire population are described in Section “Statistical Methods.” In Section “An Example (for a Non-Inferiority Situation),” an example concerning a multiregional study involving a regional regulatory submission is discussed to illustrate the proposed statistical methods. Some concluding remarks are given at the end of this article.

ISSUES IN MRCTS

A multiregional clinical study is a trial conducted at more than one distinct region where the data collected from these centers are intended to be analyzed as a whole. Within a given region, the trial may be conducted as either a single-site study or a multi-center trial. In a multiregional trial, some practical issues are commonly encountered due to potential differences among centers within region and differences between regions.

Multicenter Trials

A multi-center trial is a trial conducted at more than one distinct center where the data collected from these centers are intended to be analyzed as a whole. At each center, an *identical* study protocol is used. A multicenter trial is a trial with a center or site as a natural blocking or stratified variable that provides replications of clinical results. It should permit an overall estimation of the treatment difference for the targeted patient population across various centers. For a multi-center trial, the Food and Drug Administration (FDA) guideline suggests that individual center results should be presented. In addition, the FDA suggests that statistical tests for homogeneity across

centers (i.e., for detecting possible treatment-by-center interaction) be performed. Any extreme or opposite results among centers should be noted and discussed. If there is no treatment-by-center interaction, the data can be pooled for analysis across centers.

Another issue is related to the use of a central laboratory for testing of samples collected from different centers, which may have a significant impact on the assessment of efficacy and safety of the test treatment under investigation. A central laboratory provides a consistent assessment for laboratory tests. If a central laboratory is not used, the assessment of laboratory tests may differ from center to center depending on the equipment, analyst, and laboratory normal ranges used at that center. In such a case, possible confounding and interaction effects makes it difficult to combine the laboratory values obtained from the different centers for an unbiased assessment of the safety and efficacy of the test treatment.

For statistical analysis of data collected from a multi-center trial, if there is no evidence of treatment-by-center interaction, the data can be pooled for analysis for an overall assessment of the treatment effect across centers. Along this line, Nevius^[9] proposes a set of four conditions under which evidence from a multi-center trial would provide sufficient statistical evidence of efficacy. These conditions are summarized as follows:

1. The combined analysis shows significant results.
2. There is consistency over centers in terms of direction of results.
3. There is consistency over centers in terms of producing nominally significant results in centers with sufficient power.
4. Multiple centers show evidence of efficacy after adjustment for multiple comparisons.

Multiregional, Multi-center Trials

Unlike a single multi-center trial within a given region, a multiregional trial is much more complicated, which involves several multi-center trials from different regions. In addition to those practical issues that are commonly seen in a multi-center trial, there are more critical issues that may have an impact on the assessment of treatment effect in global pharmaceutical/clinical development. These issues include, but are not limited to, potential differences in (1) study requirements (due to different regulatory requirements, see [Table 1](#) as an example), (2) ethnic factors, (3) culture, and (4) medical practice or perception in different regions. Thus, in practice, it is suggested that critical issues such as representativeness, bias/variation control, heterogeneity (similarities and dissimilarities), consistency, and poolability across regions, which may have an impact on the validity of the multiregional trial, must be carefully evaluated in order to provide an overall assessment of the test treatment under investigation.

Table 1 Examples of different regional requirements

Regional requirement	European Medicines Agency	US FDA
NI margin (HIV-infected patients)	10%–15%	10%–12%
Time points (HIV-RNA level)	16 weeks	24 weeks
Endpoint (atrial fibrillation)	Prevention of any recurrence	Delay in symptomatic recurrence
Endpoint (hepatitis B virus)	Combined composite of virological, histological, and biochemical responses	Complete virological response at 52 weeks

In practice, it is often a concern that only positive clinical results are observed in global population (i.e., all regions combined), and yet some regions (i.e., subpopulations) fail to show positive results or show positive results with insufficient power. This inconsistency, if it is not purely due to chance, is a concern for regional (local) registration. As inconsistency may be due to the fact that studies conducted at different regions may be conducted with similar but different (1) study requirements, (2) drug products and doses, (3) patient populations with different ethnic factors, (4) sample sizes, and (5) evaluability criteria, regional regulatory agencies often request the inconsistency be carefully evaluated during the regulatory review and approval process.

For evaluation of consistency, the sponsors can use a null hypothesis of consistency, and then the alternative hypothesis of inconsistency is concluded if the null hypothesis is rejected (often with insufficient power for establishing non-inferiority (NI) or similarity between the subpopulation and the entire population). It should be noted that regional regulatory agencies are not likely to accept this assessment with limited number of subjects available in a region. On the other hand, the regional regulatory agencies may accept the conclusion that there is little evidence to demonstrate that the subpopulation is inconsistent with the entire population. As a result, an additional clinical study may be required to be conducted on the subpopulation in the region in order to confirm the consistency or similarity between the subpopulation and the entire population. As an alternative, we can use a null hypothesis of inconsistency or use one of the other estimation-based methods described in this article.

STATISTICAL METHODS

As mentioned in the “Introduction” section, several methods that have been proposed in the literature in different context could be useful for evaluation of consistency between a subpopulation and the entire population in

multiregional studies. These methods are briefly outlined in the subsequent sections.

Test for Consistency

For an MTCT involving K regions, denote by $W = \{W_1, \dots, W_K\}$ the results of the multiregional trial, where W_i is the standardized test statistics observed from the i th region. To determine whether the local results from a given region is consistent with the global results, Shih^[2] proposed to construct a predictive probability function, $P(v|W)$, where v is the study conducted at a given region. The predictive probability $P(v|W)$ provides a measure of the plausibility of v given the results of W . Thus, Shih's test for consistency is summarized next.

For a given region i , we first construct the predictive probability function, $P(W_i|W)$, of the results observed from the region. We then compare $P(W_i|W)$ with the plausibility of each of the results from other regions, i.e., $P(W_j|W)$, where $j \neq i$ and $j = 1, \dots, K$. We conclude that the results of W_i is consistent with $W = \{W_1, \dots, W_K\}$ if and only if

$$P(W_i|W) \geq \min \{P(W_j|W), j \neq i, j = 1, 2, \dots, K\}. \quad (1)$$

To accommodate the superiority test with the case of the smaller the better, the method can be modified as

$$W_i - W \leq \max \{W_j - W, j \neq i, j = 1, 2, \dots, K\}.$$

If the above inequality holds, we conclude that the results of W_i are consistent with $W = \{W_1, \dots, W_K\}$.

To accommodate the superiority test with the case of the larger the better, the method can be modified as

$$W_i - W \geq \min \{W_j - W, j \neq i, j = 1, 2, \dots, K\}.$$

If the above inequality holds, we conclude that the results of W_i are consistent with $W = \{W_1, \dots, W_K\}$.

Assessment of Consistency Index

Let U and W be the measures of the primary study endpoint (treatment effects) of a given MRCT from a subpopulation (e.g., a specific region) and the global population (i.e., all regions combined), respectively, where $X = \log U$ and $Y = \log W$ follow normal distributions with means μ_x , μ_y , and variances V_x , V_y , respectively. Similar to the idea of using $P(X < Y)$ to assess reliability in statistical quality control,^[10,11] Tse et al.^[3] proposed the following probability as an index to assess the consistency of clinical results observed from the sub-population as compared to the global population

$$p = P\left(1 - \delta < \frac{U}{W} < \frac{1}{1 - \delta}\right), \quad (2)$$

where $0 < \delta < 1$ and is defined as a limit that allows for consistency. Tse et al.^[3] referred to p as the consistency index.

Thus, p tends toward 1 as δ tends toward 1. For a given δ , if p is close to 1, materials U and W are considered to be similar or approximately identical. It should be noted that a small δ implies the requirement of a high degree of consistency between measure U and measure W . In practice, it may be difficult to meet this narrow specification for consistency. Under the normality assumption of $X = \log U$ and $Y = \log W$, Eq. 2 can be rewritten as

$$\begin{aligned} p &= P(\log(1-\delta) < \log U - \log W < -\log(1-\delta)) \\ &= \Phi\left(\frac{-\log(1-\delta) - (\mu_x - \mu_y)}{\sqrt{V_x + V_y}}\right) \\ &\quad - \Phi\left(\frac{\log(1-\delta) - (\mu_x - \mu_y)}{\sqrt{V_x + V_y}}\right). \end{aligned}$$

where $\Phi(z_0) = P(Z < z_0)$ with Z being a standard normal random variable. Therefore, the consistency index p is a function of the parameters $\theta = (\mu_x, \mu_y, V_x, V_y)$, i.e., $p = h(\theta)$. Suppose that observations $X_i = \log U_i, i = 1, \dots, n_x$ and $Y_i = \log W_i, i = 1, \dots, n_y$ are collected in an assay study. Then, using the invariance principle, the maximum likelihood estimator of p can be obtained as

$$\hat{p} = \Phi\left(\frac{-\log(1-\delta) - (\bar{X} - \bar{Y})}{\sqrt{\hat{V}_x + \hat{V}_y}}\right) - \Phi\left(\frac{\log(1-\delta) - (\bar{X} - \bar{Y})}{\sqrt{\hat{V}_x + \hat{V}_y}}\right), \quad (3)$$

where $\bar{X} = \frac{1}{n_x} \sum_{i=1}^{n_x} X_i$, $\bar{Y} = \frac{1}{n_y} \sum_{i=1}^{n_y} Y_i$, $\hat{V}_x = \frac{1}{n_x} \sum_{i=1}^{n_x} (X_i - \bar{X})^2$, and $\hat{V}_y = \frac{1}{n_y} \sum_{i=1}^{n_y} (Y_i - \bar{Y})^2$. In other words, $\hat{p} = h(\hat{\theta}) = h(\bar{X}, \bar{Y}, \hat{V}_x, \hat{V}_y)$. Furthermore, it can be easily verified that the following asymptotic result holds. Tse et al.^[3] showed that $\hat{p}$ is asymptotically normal with mean $E(\hat{p})$ and variance $Var(\hat{p})$, where $E(\hat{p}) = p + B(p) + o\left(\frac{1}{n}\right)$ and $Var(\hat{p}) = C(p) + o\left(\frac{1}{n}\right)$. The detailed expressions of $B(p)$ and $C(p)$ are given in the work of Tse et al.^[3] In other words,

$$\frac{\hat{p} - E(\hat{p})}{\sqrt{Var(\hat{p})}} \rightarrow N(0, 1).$$

Hypotheses testing of the consistency index p can also be conducted based on the asymptotic normality of $\hat{p}$. Consider the following hypotheses:

$$H_0 : p \leq p_0 \text{ vs } H_1 : p > p_0.$$

We can choose p_0 as a pre-specified constant, say 0.8. Also, we recommend the value of some proportion (say 0.8)

multiplying the $\hat{p}$ of the corresponding reference–reference test. Intuitively, the latter has more reference value, i.e., it is obtained from the evidence of the corresponding reference–reference test that can be seen as some reference standard, and we name it as the R–R choice.

We would reject the null hypothesis in favor of the alternative hypothesis of consistency. Under H_0 , we have

$$\frac{\hat{p} - p_0 - B(\hat{p})}{\sqrt{Var(\hat{p})}} \sim N(0, 1). \quad (4)$$

Thus, we reject the null hypothesis H_0 at the α level of significance if

$$\frac{\hat{p} - p_0 - B(\hat{p})}{\sqrt{Var(\hat{p})}} > Z_\alpha.$$

This is equivalent to rejecting the null hypothesis H_0 when

$$\hat{p} > p_0 + B(\hat{p}) + Z_\alpha \sqrt{Var(\hat{p})}.$$

For a superiority test, we are probably more concerned with $p = P\left(\frac{U}{W} < \frac{1}{1-\delta}\right)$. A similar procedure to testing the consistency can be derived. For simplicity, we do not give the details here.

Note that this method only applies to the endpoints following lognormal distribution.

Evaluation of Sensitivity Index

In an MRCT, denote the mean and standard deviation of the target endpoint of the entire population (all regions combined) by μ_2 and σ_2 , respectively. Similarly, denote these of the subpopulation (a or some specific region(s)) by μ_1 and σ_1 . Since the two populations are similar but slightly different, it is reasonable to assume that $\mu_1 = \mu_2 + \varepsilon$ and $\sigma_1 = C\sigma_2$ ($C > 0$), where ε is referred to as the shift in location parameter (population mean) and C is the inflation factor of the scale parameter (population standard deviation). Thus, the (treatment) effect size adjusted for standard deviation of the subpopulation (μ_1, σ_1) can be expressed as follows:

$$\delta_1 = \left| \frac{\mu_1}{\sigma_1} \right| = \left| \frac{\mu_2 + \varepsilon}{C\sigma_2} \right| = |\Delta| \left| \frac{\mu_2}{\sigma_2} \right| = |\Delta| \delta_2,$$

where $\Delta = \frac{1 + \varepsilon/\mu_2}{C}$ and δ_2 is the effect size adjusted for the standard deviation of the entire population (μ_2, σ_2). Δ is referred to as a sensitivity index measuring the change in effect size between the subpopulation and the entire population.^[4]

As it can be seen, if $\varepsilon = 0$ and $C = 1$ then $\delta_1 = \delta_2$. That is, the effect sizes of the two populations are identical.

Applying the concept of bioequivalence assessment, we can claim that the effect sizes of the two patient populations are consistent if the confidence interval of $|\Delta|$ is within (80%, 120%).

In practice, the shift in location parameter (ε) and/or the change in scale parameter (C) could be seen as random. If both ε and C are fixed, the sensitivity index can be assessed based on the sample means and the sample variances obtained from the entire population and the subpopulation. As indicated by,^[4] ε and C can be estimated by $\hat{\varepsilon} = \hat{\mu}_1 - \hat{\mu}_2$ and $\hat{C} = \hat{\sigma}_1 / \hat{\sigma}_2$, respectively, where $(\hat{\mu}_2, \hat{\sigma}_2)$ and $(\hat{\mu}_1, \hat{\sigma}_1)$ are some estimates of (μ_2, σ_2) and (μ_1, σ_1) based on the entire population and the subpopulation, respectively. Consequently, the sensitivity index Δ can be estimated by $\hat{\Delta} = \frac{1 + \hat{\varepsilon} / \hat{\mu}_2}{\hat{C}}$, and the corresponding confidence interval can be obtained based on normal approximation.^[4,12]

In real-world problems, however, ε and C could be either fixed or random variables. In other words, there are three possible scenarios: (1) the case where ε is random and C is fixed, (2) the case where ε is fixed and C is random, and (3) the case where both ε and C are random. Statistical inference of Δ under each of these possible scenarios has been studied by Lu et al.^[12]

Besides, we also give a simplified version: if $\hat{\Delta}$ is within (80%, 120%), the consistency is claimed. For superiority tests, the criterion can be $\hat{\Delta} > 80\%$.

Achieving Reproducibility and/or Generalizability

Alternatively, Shao and Chow^[5] proposed the concept of reproducibility and generalizability probabilities for assessing consistency between specific subpopulations and the global population. If the influence of the ethnic factors is negligible, then we may consider the reproducibility probability to determine whether the clinical results observed in a patient population are reproducible in a different patient population. If there is a notable ethnic difference, the concept of generalizability probability can be used to determine whether the clinical results observed in a patient population can be generalized to a similar but slightly different patient population due to the differences in ethnic factor.

Modified from the original definitions of reproducibility and generalizability probabilities, we proposed three methods for normal-based test procedure and power calculation. The versions for t -distribution-based test procedure and power calculation can similarly be derived.

Specificity reproducibility probability for inequality test: If we are concerned with the null hypothesis $H_0: \mu_1 = \mu_2$ and the alternative hypothesis $H_1: \mu_1 \neq \mu_2$, where μ_1 and μ_2 are the means of treatment effects of a region and the global area (excluding the region of interest), respectively. Denote σ_1^2 and σ_2^2 as the variances of

treatment effects of the region and the global area (excluding the region of interest), respectively. Consider the case without the assumption of equal variance. When both sample sizes n_1 and n_2 are large, an approximate α level test rejects H_0 when $|T| > z_{1-\alpha/2}$, where

$$T = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{\left(\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}\right)}}$$

and $z_{1-\alpha/2}$ is the $1-\alpha/2$ quantile of the standard normal distribution. Since T is approximately distributed as $N(\theta, 1)$ with

$$\theta = \frac{\mu_1 - \mu_2}{\sqrt{\left(\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}\right)}}$$

with a pre-specified level of β (say 0.2), we get the two-sided $1-\beta$ confidence interval for θ as

$(\hat{\theta}_- - \hat{\theta}_+) = \left(T - z_{1-\beta/2}, T + z_{1-\beta/2}\right)$. Then we get two types of

one-sided $1-\beta$ confidence upper bound for $|\theta|$, denoted as $|\hat{\theta}_+^1|$ and $|\hat{\theta}_+^2|$: the first is $\max\{|\hat{\theta}_-|, |\hat{\theta}_+|\}$; the second is the non-negative value v satisfying $P\{|\theta| \leq v | T\} = 1 - \beta$, which is equivalent to the equation of $\Phi(v - T) - \Phi(-v - T) = 1 - \beta$, with $\Phi(\Delta)$ being the distribution function of the standard normal distribution. We define specificity reproducibility probability (with $|\hat{\theta}_+^j|$ taken as the true value of $|\theta|$, and standing for a unfavorable case for $|\theta|$ to some extent) as

$$P\left\{|T| \leq z_{1-\frac{\alpha}{2}} | |\hat{\theta}_+^j|\right\}, j = 1, 2,$$

which is equal to $\Phi\left(z_{1-\frac{\alpha}{2}} - |\hat{\theta}_+^j|\right) - \Phi\left(-z_{1-\frac{\alpha}{2}} - |\hat{\theta}_+^j|\right)$. Compare the specificity reproducibility probability with a pre-specified constant (say 0.8), or the value of the R-R choice mentioned previously. If the specificity reproducibility probability is larger, we conclude that the consistency holds.

Superiority reproducibility probability: With respect to the superiority test with the case of the smaller the better, consider the null hypothesis $H_0: \mu_1 \geq q * \mu_2$ and the alternative hypothesis $H_1: \mu_1 < q * \mu_2$, where q is a pre-specified constant (say 0.5). The notations here have the same meanings as those in the previous paragraph. We have

$$T = \frac{\bar{x}_1 - q\bar{x}_2}{\sqrt{\left(\frac{s_1^2}{n_1} + \frac{q^2 s_2^2}{n_2}\right)}}$$

and

$$\theta = \frac{\mu_1 - q\mu_2}{\sqrt{\left(\frac{\sigma_1^2}{n_1} + \frac{q^2\sigma_2^2}{n_2}\right)}}.$$

The rejection region is $\{T < z_\alpha\}$. The one-sided $1 - \beta$ confidence upper bound for θ , denoted as $\hat{\theta}_+$, is $T + z_{1-\beta}$. The superiority reproducibility probability is defined as

$$P\{T < z_\alpha | \hat{\theta}_+\} = \Phi(z_\alpha - \hat{\theta}_+) - \Phi(z_\alpha - T - z_{1-\beta}).$$

Compare the superiority reproducibility probability with a pre-specified constant (say 0.8), or the value of the R-R choice mentioned previously. If the superiority reproducibility probability is larger, we conclude that the consistency holds.

Reproducibility probability ratio for inequality test: For the null hypothesis $H_0: \mu_1 = \mu_2$ and the alternative hypothesis $H_1: \mu_1 \neq \mu_2$, where μ_1 and μ_2 are the means of the treatment and the reference for a specific region (or the global area). Denote σ_1^2 and σ_2^2 as the variances of the treatment and the reference for a specific region (or the global area), respectively. Consider the case without the assumption of equal variance. When both sample sizes n_1 and n_2 are large, an approximate α level test rejects H_0 when $|T| > z_{1-\alpha/2}$, where

$$T = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{\left(\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}\right)}}$$

and $z_{1-\alpha/2}$ is the $1 - \alpha/2$ quantile of the standard normal distribution. Since T is approximately distributed as $N(\theta, 1)$ with

$$\theta = \frac{\mu_1 - \mu_2}{\sqrt{\left(\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}\right)}},$$

the reproducibility probability by using the estimated power approach is given by

$$\hat{P} = \Phi(T - z_{1-\alpha/2}) - \Phi(-T - z_{1-\alpha/2}).$$

Denote $\hat{P}_S$ and $\hat{P}_G$ as the reproducibility probabilities for a region and the global area, respectively. If $\hat{P}_S/\hat{P}_G \geq q$, where q is a pre-specified constant, then the consistency of the region's results and the global results is concluded.

Besides, the reproducibility probability by using the confidence bound approach can be used as in the literature

of Shao and Chow,^[5] and the same criterion for testing consistency as above applies.

Reproducibility probability ratio for superiority test: Similar to the reproducibility probability ratio for inequality test, we can also consider the ratio for superiority test (with the case of the larger the better): $H_0: \mu_1 \geq \mu_2$ vs. $H_1: \mu_1 < \mu_2$. After obtaining the ratios for the region and the global area, the same criterion for testing consistency applies.

Bayesian Approach

For testing consistency or similarity between clinical results observed from a subpopulation and those obtained from the global population, Chow and Hsiao^[7] proposed the following Bayesian approach through the following hypothesis:

$$H_0: \Delta \geq 0 \text{ vs. } H_a: \Delta < 0,$$

where $\Delta = \mu_1 - \mu_2$, in which μ_1 and μ_2 are the population means of the treatment effects of the subpopulation and the global population, respectively. Let X_i and Y_j , $i = 1, 2, \dots, n$ and $j = 1, 2, \dots, N$, be some efficacy responses observed in the subpopulation and the global population, respectively. For simplicity, assume that both X_i s and Y_j s are normally distributed with known variance σ^2 . When σ^2 is unknown, it can generally be estimated by the sample variance. Thus, Δ can be estimated by

$$\hat{\Delta} = \bar{x} - \bar{y},$$

where $\bar{x} = \sum_{i=1}^n x_i/n$ and $\bar{y} = \sum_{j=1}^N y_j/N$. Under the following mixed prior information for Δ ,

$$\pi = \gamma\pi_1 + (1-\gamma)\pi_2,$$

which is a weighted average of two priors, where $\pi_1 \equiv c$ is a non-informative prior and π_2 is a normal prior with mean θ_0 and variance σ_0^2 , and γ is defined as the weight with $0 \leq \gamma \leq 1$. For the consistency test between a specific region and the global area, the choice of (θ_0, σ_0^2) can be derived from the values of $\hat{\Delta}$ from all regions except the specific region. Thus, the marginal density of $\hat{\Delta}$ is given by

$$m(\hat{\Delta}) = \gamma + (1-\gamma) \frac{1}{\sqrt{2\pi(\sigma_0^2 + \tilde{\sigma}^2)}} \exp\left\{-\frac{(\hat{\Delta} - \theta_0)^2}{2(\sigma_0^2 + \tilde{\sigma}^2)}\right\},$$

where $\tilde{\sigma}^2 = \sigma^2\left(\frac{1}{n} + \frac{1}{N}\right)$. Given the clinical data and prior distribution, the posterior distribution of Δ is

$$m(\Delta|\hat{\Delta}) = \frac{1}{m(\hat{\Delta})} \left\{ \gamma \frac{1}{\sqrt{2\pi\tilde{\sigma}^2}} \exp\left[-\frac{(\Delta - \hat{\Delta})^2}{2\tilde{\sigma}^2}\right] + (1-\gamma) \frac{1}{2\pi\sigma_0\tilde{\sigma}} \exp\left[-\frac{(\Delta - \theta_0)^2}{2\sigma_0^2} - \frac{(\Delta - \hat{\Delta})^2}{2\tilde{\sigma}^2}\right] \right\}.$$

Thus, given the data and prior information, similarity (consistency) on efficacy in terms of a positive treatment effect for the subpopulation can be concluded if the posterior probability of consistency (similarity) is

$$p_c = P(\mu_1 - \mu_2 > 0 | \text{clinical data and prior}) \\ = \int_{-\infty}^0 \pi(\Delta | \hat{\Delta}) d\Delta > 1 - \alpha.$$

For some pre-specified $0 < \alpha < 0.5$. In practice, α is determined such that the subpopulation is generally smaller than 0.2 to ensure that the posterior probability of consistency is at least 80%. Besides, the R-R choice can be compared with p_c .

Based on the discussion given in the work of Chow and Hsiao,^[7] the marginal density of $\hat{\Delta}$ can be re-expressed as

$$m(\hat{\Delta}) = \gamma + (1 - \gamma) \frac{1}{\sqrt{2\pi(\sigma_0^2 + 2\sigma^2/N)}} \\ \exp \left\{ -\frac{(\hat{\Delta} - \theta_0)^2}{2\left(\sigma_0^2 + \frac{2\sigma^2}{N}\right)} \right\}.$$

As a result, the posterior distribution of Δ is therefore given by

$$m(\Delta | \hat{\Delta}) = \frac{1}{m(\hat{\Delta})} \left\{ \gamma \frac{1}{\sqrt{4\pi\sigma^2/N}} \exp \left[-\frac{(\Delta - \hat{\Delta})^2}{4\sigma^2/N} \right] + (1 - \gamma) \frac{1}{\sqrt{8\pi\sigma_0^2\sigma^2/N}} \exp \left[-\frac{(\Delta - \theta_0)^2}{2\sigma_0^2} - \frac{(\Delta - \hat{\Delta})^2}{4\sigma^2/N} \right] \right\}.$$

Consequently, we have

$$p_c = \int_{-\infty}^0 \pi(\Delta | \hat{\Delta}) d\Delta > 1 - \alpha.$$

Japanese Approach

In a multiregional trial, to establish the consistency of treatment effects between the Japanese population and the entire population under study, the Ministry of Health, Labour and Welfare (MHLW)^[1] of Japan suggested evaluating the relative treatment effect (i.e., treatment effect observed in Japanese population compared to that of the entire population) to determine whether the Japanese population has achieved a desired assurance probability for consistency.

Let μ be the treatment effect of the test treatment under investigation. Denote by μ_1 and μ_2 the treatment effect of the Japanese population and the treatment effect of the entire population (all regions), respectively. Let $\hat{\mu}_1$ and $\hat{\mu}_2$

be the corresponding estimators. For an MRCT, given μ , the sample size ratio (i.e., the size of Japanese population compared to the entire population), and the overall result being is significant at the α level of significance, the assurance probability, p_a , of consistency is defined as

$$p_a = P_\delta \left(\hat{\mu}_1 \leq \frac{1}{\rho} \hat{\mu}_2 | Z \right) z_{1-\alpha} > 1 - \gamma,$$

where Z represents the overall test statistic, ρ is the minimum requirement for claiming consistency, and $0 < \gamma \leq 0.2$ (denote $p_0 = 1 - \gamma$) is a pre-specified desired level of assurance. The Japanese MHLW suggests that ρ be ≥ 0.5 . The determination of ρ , however, should be different from product to product.

In practice, the above required sample size may either not be easy to be achieved or not pre-planned. Instead, consistency may be evaluated using the above idea of the effect of a subpopulation achieving a specified proportion (usually $\geq 50\%$) of the observed overall effect. This can be seen as a simplified version of the Japanese approach.

The Applicability of Those Approaches

Considering the data type and which term the consistency is tested based on, the approaches have different applicability. With respect to the data type, the normal data and

binary data are two widely used types. As for the term of consistency, the following two can be considered: (1) comparing the two effects directly, e.g., comparing $\mu_{T1} - \mu_{R1}$ and $\mu_{T2} - \mu_{R2}$ directly, where (μ_{Ti}, μ_{Ri}) are the treatment mean and the reference mean for the i region, $i = 1, 2$; (2) testing the consistency in terms of the original aim, e.g., testing the consistency between $\{\mu_{T1} - \mu_{R1} < 0\}$ and $\{\mu_{T2} - \mu_{R2} < 0\}$ when the original hypothesis is $H_0: \mu_T - \mu_R \geq 0$ vs. $H_1: \mu_T - \mu_R < 0$. Table 2 shows the applicability of the approaches.

An example of direct comparison and original aim is as follows: assume a global clinical trial was carried out to compare the effect of a new drug and the effect of a reference drug globally and regionally. Denote μ_{GT} , μ_{GR} , μ_{ST} , and μ_{SR} as the means of the new drug globally, the reference drug globally, the new drug for a specific region, and the reference drug for the specific region, respectively. We were concerned with the hypothesis testing $H_0: \mu_{GT} - \mu_{GR} \geq 0$ vs $H_1: \mu_{GT} - \mu_{GR} < 0$, as well as $H_0: \mu_{ST} - \mu_{SR} \geq 0$ vs $H_1: \mu_{ST} - \mu_{SR} < 0$. To test the consistency between the global effect $\mu_{GT} - \mu_{GR}$ and the specific

region effect $\mu_{ST} - \mu_{SR}$, we may consider a variety of hypothesis testing. One is just to test $H_0: \mu_{GT} - \mu_{GR} = \mu_{ST} - \mu_{SR}$ vs $H_1: \mu_{GT} - \mu_{GR} \neq \mu_{ST} - \mu_{SR}$, which can be seen as direct comparison and is not directly related to whether $\mu_{ST} - \mu_{SR}$ is smaller than 0. Another one is directly related to $H_0: \mu_{ST} - \mu_{SR} \geq 0$ vs $H_1: \mu_{ST} - \mu_{SR} < 0$, such as the Bayesian method introduced previously which is used to estimate the posterior probability of $\{\mu_{ST} - \mu_{SR} < 0\}$ using both the specific regional data and the global data.

AN EXAMPLE (FOR A NI SITUATION)

Compared with a superiority situation, it is more difficult to evaluate the consistency for NI situations since some methods may not work directly for a NI situation and the concept for consistency is less intuitive. Let us use an event-driven trial with two treatment groups as an example to evaluate the consistency for a NI situation.

We will designate the observed hazard ratio between test drug and control drug as HR_G for the global population and HR_S for a subpopulation. The two-sided type I error rate is 5%. The trial is successful based on the global population: the upper bound of 95% confidence interval (CI) for the $HR_G < 1$ (if it is a superiority trial) or the upper bound of 95% CI for the $HR_G < NI$ margin denoted as Δ (if it is a NI trial). Conditional on the success of the overall trial, the results for the subpopulation analyses could be divided into four categories in Table 3 and interpreted as follows:

- For results in Category 1, it is clear that the subpopulation performed better than the global population. Consistency evaluation is usually not necessary.
- For results in Category 2, it is reasonable to consider the subpopulation results consistent with the global results, since a global result of the same magnitude as the subpopulation result would have given a positive study.
- For results in Category 3, consistency is less clear, since a global result of the same magnitude as the subpopulation result would not have given a positive study.
- For results in Category 4, inconsistency is observed.

Table 3 Four Categories of the Test Results

Category	Superiority trial	NI trial
1	$HR_S < HR_G$ (clearly met superiority)	$HR_S < HR_G$ (clearly met NI)
2	$HR_G < HR_S < 1$ and the upper bound of 95% CI for HR_S based on the overall number of events < 1	$HR_G < HR_S < \Delta$ and the upper bound of 95% CI for HR_S based on the overall number of events $< \Delta$
3	$HR_G < HR_S < 1$ but the upper bound of 95% CI for HR_S based on the overall number of events ≥ 1	$HR_G < HR_S < \Delta$ but the upper bound of 95% CI for HR_S based on the overall number of events $> \Delta$
4	$HR_G < 1 \leq HR_S$	$HR_G < HR_S$ and $HR_S \geq \Delta$

Categories 2 and 3 can be interpreted as answering the question: If the global study point estimate was the same as the observed subpopulation point estimate, would the global study have been positive? Please note that if there are only a few events in a subpopulation, then no meaningful consistency evaluation can be done.

Example (this does not represent the results of a particular clinical trial): A phase 3, active (denoted as drug B) controlled, randomized (1:1 ratio), double-blind, event-driven parallel arm study to evaluate the efficacy and safety of a test drug (denoted as drug A). The primary objective is to demonstrate if the test drug A is non-inferior (NI with a NI margin of 1.40 for the hazard ratio of drug A vs drug B) to the control drug B for a time-to event endpoint. The secondary objectives include superiority tests for the primary endpoint and all cause death. Thirty-eight countries (denoted as C1–C38) from four regions participated in the study. The results for the primary endpoint by country based on the intent-to-treat (ITT) are plotted in Fig. 1 and Table 4 (for selected countries). “NON ESTIMABLE” indicates that the hazard ratio could not be estimated because events did not occur in both treatment arms.

It is clear that no one will question the consistency for Country 18, e.g., since its HR is smaller than that for the

Fig. 1 Adjudicated stroke or systemic embolism during the intended treatment period, overall and by country—randomized subjects

Country C18	1,609	18 (0.96)	29 (1.52)	0.63 (0.36, 1.10)
Country C22	1,255	16 (1.13)	16 (1.24)	0.91 (0.49, 1.70)
Country C28	752	25 (3.47)	23 (3.24)	1.07 (0.63, 1.82)
Country C31	830	12 (1.35)	9 (1.01)	1.33 (0.59, 3.00)
Country C34	289	3 (0.80)	2 (0.44)	1.82 (0.30, 10.99)

global population. Although the HR for Country 22 is less than 1 and the HR for Country 28 is greater than 1, both countries belong to Category 2 since this is a NI trial (hazard ratio should be compared with the NI margin instead of 1). Country 31 belongs to Category 3. Country 34 belongs to Category 4. However, since the number of events isare very small, the results for Country 34 are inconclusive.

Let us use Country 28 and Country 31 as examples to illustrate how to use the statistical methods described in the previous sections to evaluate the consistency. First of all, the HR for Country 28 is far less than the NI margin. If this result had been observed for the global population, then the NI claim would still have been established. The consistency evaluation for Countries 28 and 31 based on

the Bayesian approach described in Section “Bayesian Approach” are listed in Table 5. The results are as expected, i.e., the posterior probabilities of consistency for Country C28 are all >80% (mean=0.90), which indicates consistency. The posterior probabilities of consistency for Country C31 are not all >80% (mean=0.69), which indicates inconsistency may exist.

Some statistical methods such as the method of Tse and Japanese approach that are described in Section “Statistical Methods” for evaluating consistency may not work directly for the NI situations when the subpopulation results and the global result are not on the same side of 1 (for hazard ratio) (or 0 for mean difference), e.g., the hazard ratios for Countries C28 and C31 are >1, but the hazard ratio for the global population is <1. However, if

Table 5 Values of posterior probability (P_c) for various values of weight (γ) for countries C28 and C31

γ	P_c for C28	P_c for C31
0.0	1.00	1.00
0.1	0.98	0.90
0.2	0.96	0.83
0.3	0.94	0.77
0.4	0.92	0.72
0.5	0.91	0.68
0.6	0.89	0.65
0.7	0.88	0.62
0.8	0.86	0.59
0.9	0.85	0.57
1.0	0.84	0.55

we know the HR and its corresponding CI for the control drug vs placebo, then indirect comparison results between the test drug and placebo could be used to evaluate consistency using these methods. For example, the hazard ratio (HR_{BvsP}) and the corresponding 95% CI between the control drug B and placebo from historical trials are 0.38 (0.26, 0.56). Assuming HR_{BvsP} for Countries 28 and 31 is the same as that for the global population, the HRs between drug A and placebo can be derived as 0.31, 0.41, and 0.51 for global, Country C28, and Country 31, respectively. Then Country C28 reserves 85.7% of the global effect (as measured by the relative risk reduction) and Country C31 reserves 71.5% of the global effect. Based on the principle of Japanese guidelines, Both Country 28 and Country 31 results are consistent with the global result. In addition, there is absence of treatment-by-region (the subpopulation X vs the rest population) interactions (the p -values for the interaction test are >0.15) for both Countries C28 and C31.

Therefore, there is no indication that Country C28 is inconsistent with the global population results from a statistical point of view. However, such a conclusion could not be made for Country 31.

OTHER CONSIDERATIONS/DISCUSSIONS

In the previous sections, we have mainly discussed the statistical methods for consistency evaluation. There are other areas for consideration of consistency evaluation. For example, if a numerical inconsistency was observed for the subpopulation data, then one could consider the following from a clinical point of view:

- Consider the severity and subtype of the events, if any, to understand the nature of the difference. For example, consider the types of hemorrhagic strokes and ischemic strokes for the stroke endpoint; cardiovascular (CV) vs non-CV deaths for all-cause death endpoint.

- Conduct sensitivity analysis such as on-treatment analysis vs ITT analysis which may help to clarify the differences. For example, if the on-treatment result for a subpopulation is consistent with the global result but the ITT results are not, then examine the post-treatment medication differences and assess if there is a dose adjustment and stabilization period needed for the post-treatment medication which may explain the difference.

Since the subpopulations are usually not powered in the MRCT, it is likely to observe numerical differences in the results for some subpopulations. It is difficult to identify the causes for the difference between the subpopulation and the global population. Therefore, we suggest that if a numerical difference is observed between a subpopulation of interest and global population, and the sample size is not very small, then perform a complete consistency evaluation (possible difference in population, pharmacokinetic/pharmacodynamics (PK/PD), statistical tools, and clinical aspects) as discussed in this article. If no appropriate causes could be found to explain the numerical difference or to show inconsistency, then the conclusion could be drawn if no inconsistency is found. It is likely due to a random chance, especially when the sample size (or total events) for the subpopulation is small. In such cases, the global results should be used for the regional approval and/or more data could be obtained either prior to or after regional approval.

CONCLUSION

In this article, we have discussed several statistical methods to evaluate consistency between a specific region (i.e., subpopulation) and all regions combined (i.e., global population or entire population). We have also illustrated how to use those methods for NI situations through an example as it is more difficult to evaluate consistency for a NI situation.

Statistical evaluation is only part of the consistency evaluation between a subpopulation and the global population. Possible differences in population, PK/PD, and clinical aspects should also be evaluated.

Since the subpopulations are usually not powered in the MRCT, it is likely to observe numerical differences in the results for some subpopulations. It is difficult to identify the causes for the difference between the subpopulation and the global population, especially when the sample size is small for the subpopulation. Therefore, for evaluation of consistency in clinical results between a specific region and all regions combined, it is suggested that power calculation for sample size should take into consideration the minimum sample size required at the specific region for achieving a desired level of consistency or assurance probability as suggested by MHLW^[1] to ensure consistency in terms of treatment effect between a subpopulation and the entire population.

Abstract

There is a rich literature available on the methods used to estimate sample size for region/country in a multi-regional clinical trial (MRCT) including the guidance from Japan's Ministry of Health, Labour and Welfare (MHLW). While a variety of methods have been studied, two approaches in the MHLW guideline, Methods 1 and 2, are the most commonly used in practice to estimate sample size. When the trial data become available and the consistency of treatment effects across regions is evaluated, the criteria used for regional sample size estimation may not be the only criteria needed to determine consistency or inconsistency. In this entry, the criteria used to estimate regional sample size and to examine consistency are both briefly reviewed. They are then contrasted to identify in what ways they are similar or dissimilar.

Keywords: Heterogeneity assumption; Regulatory and international guidelines; Trend; Planning; analysis.

INTRODUCTION

There is a rich literature available on the methods used to estimate sample size for region/country in a multi-regional clinical trial (MRCT) including the guidance from Japan's Ministry of Health, Labour and Welfare (MHLW). While a variety of methods have been studied, two approaches in the MHLW guideline, Methods 1 and 2, are the most commonly used in practice to estimate sample size. When the trial data become available and the consistency of treatment effects across regions is evaluated, the criteria used for regional sample size estimation may not be the only criteria needed to determine consistency or inconsistency. In this entry, the criteria used to estimate regional sample size and to examine consistency are both briefly reviewed. They are then contrasted to identify in what ways they are similar or dissimilar.

BACKGROUND

Traditionally, clinical trials had been conducted mainly in Western regions such as North America and Western Europe. However, recently clinical trials have become more widely globalized and often include the so-called emerging regions such as Eastern Europe, Latin America, and Asia, which is considered relatively new paradigm in simultaneous drug development. The objective of these

trials, known as multi-regional clinical trials (MRCT), is to show the effectiveness of a new drug and obtain nearly simultaneously regulatory approval in multiple regions by applying the overall trial results in each region. Regulatory guidelines⁽¹⁻³⁾ have been published to provide principles for planning and designing MRCTs.

One of the above regulatory guidelines prepared by MHLW, "Basic Principles on Global Clinical trials"⁽¹⁾ was published when the drug development paradigm in Japan shifted from the stand-alone clinical trials to MRCT with Japan as one of the participating countries to synchronize the submission timing with that of the first country to file for regulatory approval, typically the US. To guide the design of MRCTs which include Japan, the MHLW guideline⁽¹⁾ describes fundamental principles for global clinical trials including two methods to estimate Japanese sample size (Method 1 and 2).

Method 1 estimates the number of subjects in the target region to achieve a specified probability (e.g., 80%) of a consistent treatment effect by taking the ratio of that region's treatment effect to the overall treatment effect compared with a predetermined threshold (e.g., 0.5). Method 2 is a way to determine the number of subjects for each region to achieve a specified probability so that all treatment effects across regions show a similar tendency (e.g., at least favor in study drug compared to placebo).

These two methods triggered research in estimating sample sizes for Japan (and other countries), and currently

there is an abundant literature available for sample size estimation for regions in a multi-regional clinical trial. While a variety of methods have been studied, Methods 1 and 2 are the most commonly used in practice to estimate the sample size for the region of interest. The draft ICH-E17 guideline⁽³⁾ on MRCTs, which became available for public comment in July 2016, includes examples for sample size allocation to regions using Methods 1 and 2 (see the section titled, ICH-E17 Draft Guidance 2016).

When the trial is completed and the data reviewed, the consistency of treatment effects across regions is evaluated. In some cases the criteria used to determine regional sample size may not be the criteria needed to conclude whether treatment effects are consistent or inconsistent across regions. In evaluating this question of consistency, there is a certain common theme that can be delineated from various different sources such as regulatory guidelines, ICH-E17 draft guidance, scientific presentations, and past examples of evaluating consistency.

In this entry, current methods researched to estimate regional sample size will be briefly reviewed to highlight the context of the criteria. These will be compared with the criteria used to evaluate consistency of treatment effects across regions to show that these consistency criteria are not necessarily the same as the criteria used to estimate regional sample size.

CRITERIA FOR SAMPLE SIZE FOR REGION/COUNTRY

Design considerations for MRCTs, including sample size for region/country is well described in the details in the book, *Multiregional Clinical Trials for Simultaneous Global New Drug Development*, edited by Chen and Quan⁽⁴⁾ (MRCT book). In this section, some concepts of consistency which are used to estimate regional sample size in the clinical trial design stage are summarized briefly. The relationship between regional sample size and the probability for demonstrating consistency can be followed, and the details of derivations will be presented for the first criteria, and can be found in the references cited for other criteria.

Assumptions and Notations

- X_{ij} and Y_{ij} : the control and experimental treatment group endpoint values for the j th patient within region i with normal distributions:

$$X_{ij} \sim N(\mu_{ix}, \sigma_i^2) \text{ and } Y_{ij} \sim N(\mu_{iy}, \sigma_i^2), \text{ for } i = 1, \dots, s.$$

- s : number of region
- Variances are the same across groups and regions, $\sigma_1^2 = \sigma_2^2 = \dots = \sigma^2$

- N_i : the number of patients per treatment group for the i th region (1:1 treatment ratio).
- N : the total number of patients in each treatment group, $N = \sum_{i=1}^s N_i$
- f_i : the fraction of patients from region i , $f_i = \frac{N_i}{N}$
- δ_i : true treatment effect within region i , $\delta_i = \mu_{iy} - \mu_{ix}$, positive δ_i indicates better outcome for experimental group
- $\hat{\delta}_i$: estimated true treatment effect δ_i within region i , $\hat{\delta}_i = \hat{Y}_i - \hat{X}_i \sim N\left(\delta_i, \frac{2\sigma^2}{N_i}\right)$
- δ : overall treatment effect based on patients from all regions, $\delta = \sum_{i=1}^s f_i \delta_i$
- $\hat{\delta}$: a common estimate of an overall treatment effect, $\hat{\delta} = \frac{\sum_{i=1}^s N_i \hat{\delta}_i}{N} \sim N\left(\delta, \frac{2\sigma^2}{N}\right)$
- u_i : ratio of the treatment effect for region i to the overall treatment effect, $u_i = \delta_i / \delta$, and $\sum_{i=1}^s f_i u_i = 1$
- z_α : the $(1 - \alpha)$ quantile of the standard normal distribution.

Region as Fixed-Effects

Quan, Li et al.,⁽⁵⁾ classified into 5 ways to define consistency as shown below.

A Specified Proportion of the Observed Overall Effect

This criterion is similar to that used in Method 1, which estimates the number of subjects in the target region to achieve the specified probability to obtain an consistent treatment effect by taking the ratio of that region's treatment effect $\hat{\delta}_i$ to the overall treatment effect $\hat{\delta}$ compared with a predetermined threshold π (e.g. $\pi \geq 0.5$).

$$\hat{\delta}_i / \hat{\delta} > \pi.$$

Uesaka⁽⁶⁾ showed how to determine the regional sample size to achieve the required probability that would simultaneously ensure both the consistency criterion when there is a specific region of interest R_s and a significant overall treatment effect.

$$\begin{aligned} \gamma &= \Pr\left(\hat{\delta} \geq z_\alpha \sigma \sqrt{2/N}, \hat{\delta}_{R_s} > \pi \hat{\delta}\right) \\ &= \int_{z_\alpha \sigma \sqrt{2/N}}^{\infty} \frac{1}{2\sigma \sqrt{\pi/N}} \exp\left(-\frac{(x - \delta)^2}{4\sigma^2/N}\right) \Phi(-y_x) dx \end{aligned}$$

where the joint distribution of $(\hat{\delta}, \hat{\delta}_{R_s})'$ is

$$N \left(\begin{pmatrix} \delta \\ \delta_{R_S} \end{pmatrix}, 2\sigma^2 / N \begin{bmatrix} 1 & 1 \\ 1 & 1/f_{R_S} \end{bmatrix} \right),$$

Φ is the cumulative standard normal distribution function, and

$$y_x = \frac{\delta - \delta_{R_S} + (\pi - 1)x}{\sigma \sqrt{2/N f_{R_S} (1 - f_{R_S})}} \lambda.$$

The conditional probability given there is a significant overall treatment effect ^(5,7) for determining the sample size in a region of interest is

$$\Pr(\hat{\delta}_i > \pi\hat{\delta}, 1 \leq i \leq s | \hat{\delta} \geq z_\alpha \sigma \sqrt{2/N}; \delta_i, 1 \leq i \leq s).$$

Li, Quan et al.,⁽⁸⁾ developed R-code to compute the conditional probability when it is replaced with

$$\frac{\Pr(Z_i > 0, 1 \leq i \leq s; Z_{s+1} > 0 | \delta_i, 1 \leq i \leq s)}{1 - \Phi\left(z_\alpha - \delta / \sigma \sqrt{2/N}\right)}$$

where

$$Z_i = (1 - \pi f_i) \hat{\delta}_i - \pi \sum_{j \neq i} f_j \hat{\delta}_j, 1 \leq i \leq s \text{ and } Z_{s+1} = \hat{\delta} - \sigma \sqrt{2/N}.$$

The joint distribution of $(Z_1, \dots, Z_{s+1})'$ is a multivariate normal random vector with mean

$$\delta \begin{pmatrix} u_1 - \pi \\ u_2 - \pi \\ \vdots \\ u_s - \pi \\ 1 - z_\alpha \sigma \sqrt{2/N} / \delta \end{pmatrix}$$

and covariance matrix

$$\frac{2\sigma^2}{N} \begin{pmatrix} (\pi^2 - 2\pi + 1/f_1) & (\pi^2 - 2\pi) & \cdots & (\pi^2 - 2\pi) & (1 - \pi) \\ (\pi^2 - 2\pi) & (\pi^2 - 2\pi + 1/f_2) & \cdots & (\pi^2 - 2\pi) & (1 - \pi) \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ (\pi^2 - 2\pi) & (\pi^2 - 2\pi) & \cdots & (\pi^2 - 2\pi + 1/f_s) & (1 - \pi) \\ (1 - \pi) & (1 - \pi) & \cdots & (1 - \pi) & 1 \end{pmatrix}$$

Without repeating similar details, the rest of the criteria for regional sample size estimation are listed to highlight the concept.

Region Effect Exceeds a Prespecified Size

This criterion is similar to that used in Method 2, which estimates the number of subjects for each region to achieve a specified probability that all treatment effects across regions show a similar tendency (e.g., at least, results favor the study drug compared with placebo).

$$\hat{\delta}_1 > b, \hat{\delta}_2 > b, \dots \text{and } \hat{\delta}_s > b, \text{ where } b \geq 0.$$

Kawai, Chuang-Stein et al.,⁽⁹⁾ showed that the probability to ensure the criteria above depends on the treatment allocation balance within each region, treatment effect size, total sample size, number of regions, and allocation of patients among regions. Unconditional probabilities to ensure the criteria and the conditional probabilities to ensure the criteria given a significant overall treatment effect were evaluated in case of common true treatment effects across regions, i.e., $\delta_1 = \delta_2 = \dots = \delta_s = \delta$.

Region Effects Exceed a Proportion of the Overall Effect Using Hypothesis Testing

Another way to assess consistency of regional effect is to use a hypothesis testing framework similar to Liu and Chow⁽¹⁰⁾. Consistency is considered if H_0 is rejected and H_1 is accepted.

$$H_0 : \delta_1 \leq \pi\delta \text{ or } \dots \text{or } \delta_s \leq \pi\delta \text{ versus, } H_1 : \delta_1 > \pi\delta \text{ and } \dots \text{and } \delta_s > \pi\delta$$

Absence of Significant Treatment-by-Region Interaction

This popular approach to assess treatment-by-subgroup interaction is also applicable to test inconsistency of regional effect when H_0 is rejected and H_1 is accepted.

$$H_0 : \delta_1 = \delta_2 = \dots = \delta_s = \delta \text{ versus, } H_1 : \delta_i, \\ i = 1 \dots s, \text{ are not all the same.}$$

This can be tested using Cochran's Q type statistic test statistic^(4,5) derived from the same manner as in the meta-analysis.⁽¹¹⁾

Lack of Significant Difference for Any Regions from the Overall

This is a one-sided version of previous criteria. If H_{0i} is rejected and H_{1i} is accepted the region i effect is not considered consistent with the overall effect, and therefore consistency across all regions has not been shown.

$$H_{0i} : \delta_i \geq \delta \text{ versus } H_{1i} : \delta_i < \delta, i = 1, \dots, s.$$

ICH-E17 Draft Guidance 2016

The ICH guideline on MRCTs has been developed, and the draft guideline⁽³⁾ became available for public comment in July 2016. The ICH-E17 draft guideline⁽³⁾ lists five examples for sample size allocation to regions.

- i. show similar trends in treatment effects across regions
- ii. determine the regional sample size to show that the regional treatment effect meets a pre-specified proportion of the overall treatment effect
- iii. determine the regional sample size in proportion to region size and disease prevalence without requiring a prespecified allocation for regions
- iv. determine the regional sample sizes to achieve significant results within a region
- v. require a specific number of subjects.

These approaches are not entirely new and have been introduced or discussed in guidelines or at professional/scientific forums. Approaches i. and ii. share concepts similar to those of Japanese Method 2 and Method 1, respectively. Approach iii. was discussed at the ICH scientific and regulatory workshop in 2015⁽¹²⁾ held by the MRCT center of Brigham and Women's hospital, and at Harvard and Peking University. Approach iv. is the most conservative approach, which may be required for stand-alone local trials. Finally, approach v. is sometimes accepted as a feasible number of subjects when recruitment is considered difficult due to prevalence and site availability for the particular disease in a certain region.

Region as Random-Effects

In MRCTs, a random-effects model is introduced to estimate robust total sample size^(13,14). The random effects model treats true regional treatment effects as random variables. δ_i 's are assumed to have variability, exchangeable, and follow the same distribution:

$$\hat{\delta}_i | \delta_i \sim N\left(\delta_i, \frac{2\sigma^2}{N_i}\right) \text{ and } \delta_i \sim N(\delta, \tau^2)$$

where

δ : overall population mean

τ^2 : between region variability.

Or unconditionally

$$\hat{\delta}_i \sim N\left(\delta, \frac{\tau^2 + 2\sigma^2}{N_i}\right).$$

The observed overall sample treatment effect from a random-effect model follows a distribution

$$\hat{\delta} = \sum_{i=1}^s f_i \hat{\delta}_i \sim N\left[\delta, \sigma^2 \left(\frac{2}{N} + \left(\frac{\tau}{\sigma} \right)^2 \sum_{i=1}^s f_i^2 \right)\right].$$

The regional sample size can then be obtained from the following formula of the total sample size per treatment group with the fraction of patients for region i , $f_i = N_i/N$.

$$N_R = \left[\frac{1}{2} \left(\left(\frac{\delta}{\sigma(z_\alpha + z_\beta)} \right)^2 - \left(\frac{\tau}{\sigma} \right)^2 \sum_{i=1}^s f_i^2 \right) \right]^{-1}.$$

If $\tau^2 = 0$ is assumed, then the resulting total sample size per treatment group

$$N_F = \frac{2\sigma^2(z_\alpha + z_\beta)^2}{\delta^2}.$$

Quan, Li et al.,⁽¹⁴⁾ proposed an empirical shrinkage estimator based on the random-effects model for individual regions. They showed the probabilities for simultaneously showing significance of the overall treatment effect and consistency of treatment effect determined based on the criteria of Japanese Method 1 or Method 2 by using a simple random-effects model or an empirical shrinkage estimator, respectively. Information from the other regions is used, with the shrinkage estimator being a weighted average of the estimators of the regional treatment effect and the overall treatment effect. Quan, Mao et al.,⁽¹⁵⁾ proposed the James–Stein type shrinkage estimator associate with smaller variability compared with the regular sample estimator. The relationship between the value of τ^2 and the sample size for a random-effects model can be found in Quan, Mao et al.,⁽¹⁵⁾. They showed the number of regions should not be too small to obtain a desirable type I error.

To allow between-region variability in the model, the overall sample size using the random effects model is typically larger than that of the fixed effects model.

CONSISTENCY EXAMINATION OF TREATMENT EFFECTS ACROSS REGIONS

In examining consistency of treatment effects across regions, a typical approach is to test treatment-by-region interaction as in the general subgroup examination. Chen, Quan et. al.,⁽¹⁶⁾ provided a systematic review of the existing methods to assess consistency of treatment effects across regions and classified the methods into global methods (single statistic), quantitative methods, and qualitative methods. Quantitative methods assess variation in the magnitude but not in the direction of the treatment effects among regions, and qualitative methods assess the opposite direction of treatment effects among regions. We reviewed recommendations on how to examine consistency of treatment effects across regions from multiple sources (ICH-E5, ICH-E17 draft, EMA draft guideline on subgroup, publication, presentation). A point to notice is that the criteria used for calculating the regional sample size in the planning stage may not be the determining criteria to conclude consistency in the data interpretation stage. The EMA draft guideline on the investigation of subgroups⁽¹⁷⁾ (2014) states that, “There is no widely accepted definition for consistency”. This might be due to an essential difficulty in pre-determining one dimensional measurement to judge consistency. While many considerations for the bridging criteria were proposed after ICH-E5 guideline⁽²⁾ was introduced (1998), no established method has been realized. The tenth question and answer in the [appendix D](#) (in Japanese) for the ICH-E5 states that *it’s impossible to suggest a concrete, always applicable standard to demonstrate that the data is “similar” or “not significantly different”*. This discussion could similarly apply to the consistency criteria for MRCTs. Uyama⁽¹⁸⁾ (2012) presented a review of PMDA’s evaluations of NDAs submitted in Japan based on MRCTs, including 28 submissions between 2006 and 2012. These discussions indicated that successful bridging and consistency in MRCT are based on a comprehensive, careful review of the data both on efficacy and safety. This could be rephrased as “consensus”.

Here are the main points we identified in examining consistency of treatment effects across regions from different sources.

At a series of scientific forums held to discuss different perspectives on MRCTs, O’Neil⁽¹⁹⁾ recommended the following points to be considered when addressing issues of treatment consistency:

- Any examination of inconsistency should consider
 - Multiplicity issues
 - Baseline characteristics, medical practice, and other intrinsic/extrinsic factors that may confound the results
- Totality of data/evidence
 - Overwhelming vs marginal overall effect
 - Consistency in other important endpoints and subgroups
 - External data (same class, same patient population, etc.).

From the Japanese regulatory review on MRCT data for new drug applications, Uyama⁽¹⁸⁾ recommended

- Necessity of a sufficient number of Japanese subjects for appropriate evaluation. When the consistency is not observed, important to distinguish whether it was due to either small Japanese sample size or true ethnic difference.
- To consider the variability (e.g., SD) as well as a point estimate when taking account of small regional sample size
- To confirm the consistency of secondary endpoint(s) and safety
- When inconsistency is observed, to carefully evaluate whether it is possible to utilize the MRCT results for evidence of efficacy and safety in Japanese population by investigating the cause using subpopulation analyses.

Recommendations from regulatory guidelines include the following:

Section 2.2.7 in the ICH-E17 draft guideline⁽³⁾ (four examples for consistency examination) recommends

“In the statistical analysis plan, to include a strategy for evaluating consistency of treatment effects across regions, and for evaluating how any observed differences across regions may be explained by intrinsic and/or extrinsic factors using approaches such as

1. Descriptive summaries
2. Graphical displays (e.g., forest plots, funnel plots)
3. Model-based estimation including covariate-adjusted analysis
4. Test of treatment by region interaction.”

Section 6.1 in the EMA draft guideline⁽¹⁷⁾ has the following recommendations on using subgroups to assess consistency or inconsistency

- Absence of statistical significance in an interaction test for treatment-by-covariate or directional consistency (i.e., all points estimates to be going in the same direction) are by themselves not sufficient to imply consistency
- Full consideration of other important factors in assessing inconsistency
- Visual inspection of a Forest plot to flag subgroup for further examination
- Lack of a formal rule to detect heterogeneity of potential interest.

There remains the challenge to resolve conflicting perspectives so that regional sample size allocation can be determined 1) to provide sufficient information for an evaluation of the extent to which the overall treatment effect applies to subjects from different regions in each regional

context which may increase total and regional numbers, and 2) to plan feasible total and regional numbers of subjects without compromising the reason for conducting MRCT. As ICH-E17 is expected to be finalized in the near future, it would be helpful guideline to remember that examining consistency is a collective, comprehensive review of all of the evidence. Current draft guideline lists approach of the examination of consistency without providing a sense of the totality of evidence, something that matters more than just the primary endpoint. This narrow approach could mislead the reader into thinking that examination of consistency should be performed in a quantitative manner, when in fact it has an essential qualitative nature.

CONCLUSION

Various criteria used to estimate regional sample size in a MRCT and consistency examination of treatment effects across regions were reviewed. In looking for the criteria for consistency examination of treatment effects across regions, various different sources such as regulatory guidelines, ICH-E17 draft guidance, scientific presentations, and past examples of evaluating consistency were evaluated. Common set of criteria identified from these various sources do not appear to be limited to any single dimension criteria used for regional sample size allocations, but rather to the totality of evidence from the trial data.

Abstract

This entry discusses different sources of multivariate data, the steps involved in meta-analysis, and models in the multivariate meta-analysis framework.

INTRODUCTION

Meta-analysis is the joint statistical analysis of results from a number of related studies to obtain an overall perspective on an effect or outcome of interest. There are often multiple dimensions to the same outcome and so it is common for outcomes to be determined by at least two measures. Studies typically report multiple estimates of the same effect. Moreover, the trend toward exhaustive decision analysis to assess health technology demands examination of multiple outcomes. There are numerous forms of multivariate effect size data, which can arise in several ways, including as a comparison of one or more treatments or interventions with a control group on at least one outcome, as multiple outcomes per study, or as the measurement of an outcome at several time points. Multivariate methods in meta-analysis account for the dependence between related outcomes and are generally preferred to univariate methods that assess each outcome separately as they typically provide more information about outcomes of interest, by borrowing strength across effects both within and across studies.

The chapter begins with a discussion of different sources of multivariate data. The steps involved in any meta-analysis are discussed, followed by a description of common univariate approaches for analysis of multivariate data in meta-analysis. Models in the multivariate meta-analysis framework are then reviewed.

SOURCES OF MULTIVARIATE DATA

Meta-analysis has become a standard statistical technique to evaluate single or multiple outcomes or to evaluate sources of variation in study results.

A meta-analysis of any form entails a range of decisions to be made at each of several steps, including

identification of relevant outcomes from studies, choice of suitable response variables to measure this outcome and how to estimate these from studies, characterization of the model relating study-specific and global covariates to these responses, identification of fixed effects and random effects, and the description of within- and between-study heterogeneity. These choices then assist with forming the specific meta-analysis model, method of estimation, and the choice of univariate or multivariate methods.

Univariate meta-analysis is usually condoned on the grounds of there being a single ideal parameter that describes the response of interest. The simplest type of meta-analysis in the univariate setting comprises calculating a weighted mean of estimates as an aggregate effect size estimate. This can be generalized to incorporate random effects to permit heterogeneity across studies, meta-regressions, and generalized linear mixed models to examine associations between effect sizes and variables that define the individual studies. These have been established in both frequentist^[1,2] and Bayesian^[3–6] frameworks.

In practice, a single parameter may not be justified to assess an outcome of interest. Often reported in studies are multiple estimates of the same effect or different dimensions of the same outcome. Moreover, the current move toward comprehensive decision analysis for assessing health technology^[7] demands examination of multiple endpoints, which provides further motivation for multivariate meta-analysis.

There are numerous forms of multivariate effect size data. A common form of dependency emerges when the studies under examination compare a particular treatment with a particular control on several outcomes. Dependency is incurred because of all outcomes being measured on each subject, which creates correlated effect sizes because of their derivation from the correlated outcome measures. This can arise, for example, when comparing cholesterol and blood pressure measures between a group treated with cholesterol

lowering medication and a group treated with a placebo. Multivariate data may also emerge from the dependence between groups for the situation comparing a particular treatment with a particular control or from a comparison of several treatment groups on a single outcome.

Multivariate data may arise when a common control is compared with at least two treatments for a particular outcome in the compared studies, consequently generating several treatment effects. The common control group in all comparisons infers dependency via the correlated effect size estimates. Similarly, multivariate data may emerge when numerous treatments are each compared with a common control in terms of their effectiveness but not directly to each other. Such mixed comparisons involve decisions concerning indirect relationships.

Multivariate data similarly emerges if an outcome is measured at several points in time. This would produce correlated scores on subjects as well as dependent control and treatment comparisons based on these scores. Dependency would also arise in a situation that an individual study assesses several independent samples with related measures, or if separate studies with similar methods or samples are compared.

Multivariate methods in meta-analysis account for the dependence between related outcomes and are generally preferred to univariate methods that assess each outcome separately.^[8,9] These methods are expected to provide more information about outcomes, by borrowing strength across effects within a study as well as across studies.

STEPS IN A META-ANALYSIS

Any meta-analysis, whether univariate or multivariate, frequentist or Bayesian involves several steps, each of which requires one or more decisions to be made:

1. Design the meta-analysis.
 - a. Identify the aim of the meta-analysis. Is it simply an aggregate point or interval estimate? Are subgroup estimates of interest? Is it important to identify sources of variation, differences in study quality, extreme events, or study rankings? Is the analysis a foundation for further studies or an end in itself? The answer to these questions will impact on all of the following decisions.
 - b. Define the outcomes of interest and corresponding covariates, confounders, and other information relevant to the meta-analysis.
 - c. Construct the meta-analysis model. The model will depend on theoretical assumptions, past results, and exploratory data analyses. It will characterize the relationships between multiple outcomes, describe within- and between-study heterogeneity, and allow for sources of uncertainty, bias, and so on.
2. Collect the data.
 - a. Define the criteria by which studies will be included in the meta-analysis. These can include accessibility, peer reviewed status, the type of information reported, the standard of bias control, and so on.
 - b. Identify the sources used to collect relevant studies. These may include databases, citations, Internet searches, personal requests, and so on.
 - c. Decide on the strategy to deal with missing data. Often the reported information is not consistently available in the required form and some imputation, calculation, or other accommodation needs to be made.
 - d. Collect the relevant studies and extract the relevant information from each study. This is often easier said than done! As the data extracted forms the foundation for the subsequent meta-analysis, it is vitally important to clearly document all such activities.
3. Undertake the analysis.
 - a. Estimate correlations between outcomes and other required measures if these are not reported.
 - b. Undertake the meta-analysis and interpret the results.
 - c. Check the inferences via a sensitivity analysis of the model inputs, and of the model itself.
 - d. As part of the sensitivity analysis, assess the impact of publication bias and other important biases and confounders.

Note that the analysis includes the crucial critical interrogation of the model inputs and outputs, and of the model structure itself. The construction of the model and the corresponding methods of analysis form the main focus of the discussion in the following sections. Before proceeding, however, we discuss two important aspects of all meta-analyses.

Fixed or Random Effects

An important task for a meta-analysis is identification of fixed effects and random effects, particularly with respect to between-study variation. This will then guide the decision between fixed-, random- or mixed-effects models. The decision can be based on empirical considerations, including heterogeneity tests of data to be analyzed or previous results from similar analyses. Alternatively, it can be justified through theoretical or structural descriptions of the variation sources in the data, or it can be purely philosophical. While some argue a fixed-effects model on the basis that overall estimates from heterogeneous studies are uninterpretable,^[10] others argue that between-study variation is a reality in almost all meta-analyses and should be taken into account in the model.^[1,11]

A common set of population effects is assumed to underlie every study for a fixed-effects model, so that each effect estimate from a study is considered a random draw from this common distribution, and all observed variation is a result of study-specific sampling variation alone. A random-effects model, in comparison, assumes that a different set of population effects underlie each study, so that a study estimate is a random draw from a study-specific population, and these population parameters are themselves drawn from an overall population with a global mean (effect) of interest. Thus the observed variation is because of sampling error within studies as well as differences among studies in design, sampling and implementation methods, demographics, treatment-specific information, and so on.

If particular between-study differences can be identified, both fixed-effects and random-effects models can be extended to include regression coefficients that relate these covariates to the study outcomes. These meta-regression models are classified as fixed when all between-study differences are explained by this set of covariates, and as random or mixed when between-study variation remains following the inclusion of predictors. Many researchers have highlighted the scientific and clinical importance of meta-regressions,^[11] especially for multivariate meta-analysis.^[12,13]

Multivariate random-effects models were found to be more realistic than the corresponding fixed-effects models in a simulation study conducted by Berkey et al.^[14] because of a failure of the fixed-effects model to explain all between-study variability. Standard errors of regression coefficients for the fixed-effects parameters were consistently underestimated, hence underestimating widths of corresponding confidence intervals and producing incorrect inferences as the null hypothesis was too often rejected.

Hence the models described are presented according to whether they comprise fixed effects or random effects. Some multivariate models apply to studies with multiple outcomes or treatments but do not generalize to both cases while other methods, which although designed for one situation, easily generalize to the other.

Correlation Estimation

Most multivariate techniques necessitate estimated correlations between outcomes, which are not typically reported in studies.^[15] A study by Chiu (Chiu, C.W. Synthesizing multiple outcome measures with missing data: a sensitivity analysis on the effect of metacognitive reading intervention. Department of Counseling, Educational Psychology, and Special Education, Michigan State University, East Lansing, MI, 1997, unpublished manuscript) reported that less than 10% of multivariate studies that assessed the effect of metacognitive therapy instruction on reading ability reported intercorrelations between the outcomes of interest.

Unreported correlations between effects can be estimated from observed data. Gleser and Olkin^[16] provide relevant formulas for multiple treatment and multiple endpoint studies separately. Variance and covariance estimates can be derived using statistical packages that perform matrix calculations such as Proc IML in SAS, SPSS, R, and so on. Numerous imputation methods are also available for missing correlations (see Ref. [17] and references therein), such as substituting the average of correlations reported in other studies. Finally, correlations among outcomes in a particular study in the meta-analysis can be utilized; Berkey, Anderson, and Hoaglin^[18] claim that correlations from one study are often closer to those unreported for the remaining studies than to zero, which is the inferred correlation when outcomes are examined separately. Alternatively, unreported correlations can be estimated from sources external to the study such as authors, published manuscripts, or funding sources.^[19] It is imperative that positive definiteness of the estimated or imputed correlation matrix be confirmed before proceeding.

UNIVARIATE APPROACHES TO MULTIVARIATE META-ANALYSIS

Meta-Analysis Based on Separate Outcomes

Multiple outcomes are often assessed through separate univariate meta-analyses.^[20] This approach may generate sensible results if the outcomes are independent or weakly correlated, or if such comparisons are not of interest.^[10,21] However, if outcomes are highly related, this approach may lead to biased estimates of the Type I error rate and standard errors.^[8,10,22,23] The type and extent of this bias depends on the type and strength of dependency between outcomes. For example, in a Monte Carlo study reported by Sohn,^[15] the effect of ignoring potential relationships between estimated effects of a study was not significant, whereas the magnitude of the variation term resulting from random errors of the multivariate effects was substantial.

Meta-Analysis Based on Summary Outcomes

It is common in practice to ignore dependence within studies by creating a summary effect size estimate per study by combining related effect sizes per study and combining this with values from other studies using methods of meta analysis for independent data.^[10,20,24] Methods of summarizing effect sizes for each study include pooling outcomes to create composite measures, or pooling raw data to create summary statistics such as averages across outcomes for each study, or choosing an individual ideal or most common outcome.^[19]

A test for homogeneous effect sizes in a study is proposed by Hedges and Olkin.^[10] The relevant test statistic is assumed to follow a chi-squared distribution under

homogeneity, supporting the adequacy of a common effect size. Optimal weights to generate pooled estimates are also presented. Gleser and Olkin^[16] present univariate approaches and composite effect sizes to combine effect sizes for both multiple treatment and multiple endpoint scenarios.

The benefit of a combined estimate is that an overall probability statement regarding treatment differences is provided. This may be reasonable when the sample size is large and the outcome measures are representative of the same underlying construct, so that the effect direction of a particular treatment is the same for all outcomes. This may not be the situation, for example, if one treatment is expected to be better for one outcome than for another.^[18] Moreover, the ability to assess effect differences for different constructs is lost when outcomes are combined or when some constructs are omitted from the data set. If estimates are highly correlated, however, pooling estimates are only slightly superior to selecting a single estimate.^[10] As a separate treatment may have differing impacts on various outcomes, it might be misleading to average effects for each study or to choose a single outcome and ignore the remaining outcomes.

Meta-Analysis Based on Data Subsets

Multiple treatments are often considered. Consider a placebo that is compared to each of two treatments. If the objective of the study is to establish the superior treatment, the trials provide only indirect information, and are referred to as mixed comparisons. Discarding data from some treatment groups is often performed in practice^[25] rather than using multivariate models for such data.

Another univariate method forms subsets of data that are independent, and individual analyses are conducted on each independent outcome. The same problems as discussed above arise because comparisons between data subsets are impacted by correlations in the original data.

The impact of dependency on meta-analysis results can be assessed by a sensitivity analysis,^[26] which involves analyses both with the inclusion and with the exclusion of multiple outcomes in each study. A rational approach comprises analysis of the initial data set with one outcome per study followed by repetitions of the analysis with additions of extra outcomes. If results are similar, the analysis involving one outcome can be reported, along with details of the sensitivity analysis. Otherwise, a multivariate approach that accounts for dependence is needed.

MULTIVARIATE APPROACHES

Notation

Effect sizes or correlations are often the measures combined in a meta-analysis. The effect size is commonly a

measure of the difference between two treatments (or a treatment and a control) and is often measured in terms of the standardized or unstandardized mean difference for continuous data, or the odds ratio, relative risk, or rate difference for binary outcomes. The vector of effects for the i th study is denoted by $\theta_i = (\theta_{i1}, \dots, \theta_{ip})$, and the corresponding vector of estimated effects by $Y_i = (Y_{i1}, \dots, Y_{ip})$, based on $n_i = (n_{i1}, \dots, n_{ip})$ observations and $i = (1, \dots, k)$.

The notation is equivalent for studies with multiple time points, with Y_{ij} here denoting measures on occasion $j = 1, \dots, p$ instead of a measure of outcome j in study i . Outcomes from different studies may have different interpretations if timing of occasions differs between studies. Consider a case in which three effects are presented for each outcome, in particular pretreatment, one month post-treatment, and six months posttreatment measures. Effect interpretations at posttreatment may depend on treatment length and timing of posttreatment measures.

The study-specific effect estimates are often assumed multivariate normal (MVN) based on the assumed distribution of the corresponding population effect (or an appropriate transformation) or on the central limit theorem, so that $Y_i \sim \text{MVN}(\theta_i, \Sigma_i)$, where Σ is the variance-covariance matrix. Gleser and Olkin^[16] derived formulas for effect sizes and variance-covariance matrices under assumptions of both homogeneity and heterogeneity for multiple-endpoint studies.

Frequentist Fixed-Effects Approaches

An early fixed-effects multivariate meta-analysis method was proposed by Hedges and Olkin^[10] in which each study was assumed to measure all outcomes. This model was extended to a meta-regression by Raudenbush, Becker, and Kalaian^[12] for data from multiple-endpoint studies. Further extensions have been proposed for survival data with measurements taken at multiple time points,^[13] data from multiple treatment studies,^[16] and data from studies that simultaneously consider multiple endpoints and multiple treatments.^[18] These approaches are briefly reviewed in this section.

The well-known ordinary least-squares (OLS) regression estimation of parameters assumes constant error variance across observations for independent data, such as for univariate data from different studies in a meta-analysis. When several correlated effect sizes are taken on each subject, heteroscedasticity arises, and the OLS estimator is still unbiased but inefficient as it is no longer the minimum variance estimator. An alternative efficient estimation method is the generalized least-squares (GLS) approach, which is of the form $Y = XB + e$, where $\text{var}(e_i) = \sigma^2(x_i)$ is not constant, and is transformed by dividing all terms by $\sqrt{x_i}$. The error term now has constant variance satisfying OLS assumptions. GLS approaches to meta-analysis have been discussed by Dear,^[13] Kalaian and Raudenbush,^[27] and Timm,^[28] among others. Multivariate

meta-analysis methods that utilize GLS with covariates have also been proposed, for example by Raudenbush, Becker, and Kalaian,^[12] Becker,^[29] and Hedges and Olkin.^[10]

Building on earlier models by Hedges and Olkin^[10] and Rosenthal,^[24] Raudenbush, Becker, and Kalaian^[12] present a fixed-effects multiple regression model for analyzing multiple continuous outcomes. The model is $Y = X\beta$, where X is a design matrix, and the regression coefficients, β , represent common effect sizes across studies, and any error in the fitted model is assumed due to sampling variation alone and is assumed normally distributed around zero. Benefits of the method include incorporating associations between outcomes in each study via study-level variance-covariance matrices that can differ between studies and adjustment for covariates at study and treatment level that may explain variation in effect sizes. For each study, the model additionally accommodates different combinations of outcomes and covariates, hence enabling effects of various treatments on different outcomes to be assessed. One stacked response variable is used for each meta-analysis, thus obviating missing values and the necessity to discard or impute these values as is typically performed with classical multivariate methods in the case that studies do not report all outcomes. Disadvantages include the need for correlations among outcomes, which typically need to be estimated. Additionally, frequentist hypothesis tests are based on the assumption of normally distributed effect sizes; so moderately large sample sizes are required to ensure this.

The model of Raudenbush, Becker, and Kalaian^[12] is extended by Dear^[13] to data at multiple time points, in particular survival proportions in a follow-up study, after adjusting for covariates at study and treatment level. This procedure involves iterative modeling of the fitted values to generate correlations among times within studies. The method also enables differing treatments per subject and trials with only one treatment or control group, which act as non-randomized historical controls.^[13] As an example, a study based on three years of data for a particular treatment and a year of data for an alternative treatment provides four outcome components in the form of survival proportions for the proposed meta-analysis.^[13] The method is still based on fixed-effects, so cannot adequately account for between-study heterogeneity. Dear^[13] recommends a logistic model using generalized estimating equations as a potential resolution.

The meta-analysis method proposed by Raudenbush, Becker, and Kalaian^[12] is used by Gleser and Olkin^[16] to model multiple continuous endpoints. The model, like the earlier method, enables differing numbers of effect sizes (from multiple treatments or endpoints) to be combined between studies. Gleser and Olkin^[30] extended this method to allow at least one treatment to be compared to a common control when information for each comparison is reported in a contingency table. Here, effect sizes are computed as

proportion differences or log odds ratios. As with Gleser and Olkin,^[16] different subsets of treatments may be utilized in different studies, creating models with correlated effect sizes and missing data. The authors suggest that effect size estimates can be obtained by weighted least-squares regression. The associated models can hence be fit using most standard statistical software packages. Alternative random-effects and Bayesian hierarchical approaches have also been proposed; see the following.

Berkey, Anderson, and Hoaglin^[18] present a fixed-effects meta-regression model to collate studies that each report multiple continuous outcomes and/or multiple treatments, allowing for study- and treatment-level covariates for one or more outcomes. As with the above methods, correlations between outcomes are required, each study can report some or all of the outcomes, and may consider some or all treatments. Comparisons that do not involve a common control group are allowed and, similar to Ref. [13], studies that comprise one treatment or control group can be included, thus allowing use of additional data. It differs from previously described methods as outcomes and differences between treatments are measured in original units instead of in terms of effect sizes, thus simplifying interpretations and allowing a wider range of applications. As this method does not apply to trials reporting only effect size data, a study reporting, for example, the proportion of patients experiencing a particular illness^[13] could not be considered.

Frequentist Random-Effects Models

A random-effects model allows potential associations among population effects and covariates to be examined. The fixed-effects GLS models are extended to include random-effects representing variation among studies among population effects that are not accounted for by the model's predictor(s). A regression model that includes covariates as fixed-effects and a random-effects error term is also referred to as a mixed-effects meta-regression, so that the general model becomes $Y = XB + u + e$, where u is the random effect.

For example, the model that combines multiple continuous endpoints across studies proposed by Gleser and Olkin^[16] has been extended to the random-effects framework by Berkey, Anderson, and Hoaglin,^[18] Kalaian and Raudenbush,^[27] Higgins and Whitehead,^[31] and Berkey et al.^[14] A similar model for surrogate markers is used by Daniels and Hughes.^[32]

Van Houwelingen, Arends, and Stijnen^[33] argue that modeling two treatments separately in a multivariate framework is more informative than the alternative of combining the treatment outcomes in a summary outcome such as a log odds ratio and combining these in the meta-analysis. Favorable comparisons are also made with DerSimonian and Laird's random-effects model^[1] in terms of distributional assumptions and trial weightings. Van Houwelingen,

Arends, and Stijnen^[33] demonstrate that this model permits baseline risk examination or control group subjects events risk as a source of heterogeneity in treatment effects across trials. This may assist, for example, with the prognosis of a subject exposed to a control treatment.

As an illustration, a multivariate random-effects model comprising two outcomes might be depicted as follows

$$\begin{pmatrix} Y^A \\ Y^B \end{pmatrix} \sim N \left(\begin{pmatrix} \theta^A \\ \theta^B \end{pmatrix}, (\Sigma + C_i) \right)$$

where Y denotes the two study-specific outcomes, Σ , the between-study covariance matrix, and C_i , the within-study diagonal covariance matrix as treatments are applied to different subjects and assumed uncorrelated. For the case that treatment difference measures are made on multiple outcomes, this is similar to the model adopted by Berkey et al.,^[14] with Y comprising a difference between the measure of two treatments on outcome A with the corresponding outcome B measure. The two outcomes are measured on the same subject and hence the covariance matrix, C_i , is now non-diagonal. Covariates can be added to this model as follows

$$\begin{pmatrix} Y^A \\ Y^B \end{pmatrix} \sim N(BX_i, \Sigma + C_i)$$

This representation can be extended easily to involve more outcomes or treatment groups.

A similar meta-analysis model was developed by McIntosh^[34] based on a two-level bivariate hierarchical regression model for treatment effects, which uses the observed rates in the control group as covariates. These models can be estimated with both maximum likelihood via the expectation-maximization algorithm and Bayesian estimation via Markov Chain Monte Carlo algorithms.^[34] Arends, Vokó, and Stijnen^[35] propose a tri-variate random-effects model, providing the first example of combining more than two outcomes. The model accommodates covariates, independent, or correlated outcomes within trials and missing outcomes.

A more general mixed model was developed by DuMouchel^[36] for the meta-analysis of dose-response estimation. This paper and later ones by the same author allow studies comprising multiple outcomes or multiple treatments to be combined, accommodating both binary and continuous outcomes, where all outcomes in a model are required to be on a common scale. This method differs to those described above as correlations between outcomes for each study are not required, because these are estimated by the model. This model extends the random-effects method of DerSimonian and Laird,^[1] enabling a combination of heterogeneous study designs. Unlike the method proposed by Gleser and Olkin^[16] for multiple treatments, no treatment or control is required to be common to

all studies. Different treatment groups can comprise results from separate groups of subjects, or from groups that are subject to several treatments. Van Houwelingen, Arends, and Stijnen^[33] also adopted a mixed model extension to their 1993 approach^[37] to investigate if the covariates at study level are related to the baseline risk via multivariate regression.

Bayesian Models

The Bayesian framework provides a flexible means to model construction via hierarchies representing different relationships between the data and parameters, and different degrees and levels of uncertainty. It permits data to borrow strength from sources of evidence across studies and outcomes, and from other sources of information such as expert opinion or other studies.^[38] Such models allow more natural inference through the posterior distributions, particularly if expectations other than the mean are of interest.^[39] For example, ranking of studies is straightforward in the Bayesian framework but much more difficult under a frequentist approach.^[38]

Dominici et al.^[40] propose a hierarchical Bayesian group random-effects model and report an applied complex meta-analysis of multiple treatments and multiple outcomes. This analysis evaluates 18 different treatments for migraine headache relief, which are grouped within three classes. Multiple heterogeneous outcomes (including continuous effect sizes, differences between pairs of continuous, and dichotomous outcomes) are reported, and multiple treatments are incorporated via relationships between different classes of treatments.

Nam, Mengersen, and Garthwaite^[41] detail a Bayesian approach to the same problem considered by Raudenbush, Becker, and Kalaian^[12] and Berkey et al.,^[14,18] focusing on multiple outcomes after adjusting for study-level covariates. Modifications and reasonable assumptions are suggested to simplify computations and results, and to conform to the type of prior distributions that are able to be handled using the WinBUGS software package (<http://www.mrc-bsu.cam.ac.uk/bugs/welcome.shtml>). In particular, WinBUGS currently only handles conjugate multivariate distributions, so the commonly used non-conjugate Wishart requires approximations for inclusion in analysis. Various constraints may also be imposed on correlations to ensure positive definiteness of the corresponding variance covariance matrix.

Three Bayesian multivariate models are proposed and compared by Nam, Mengersen, and Garthwaite.^[41] The preferred model is a full hierarchical representation of the form $Y_i \sim \text{MVN}(\theta_i, \Sigma_i)$; $\theta_i \sim \text{MVN}(XB, \Gamma)$ for $i = 1, \dots, k$, where Y_i and θ_i are p -dimensional vectors of outcomes. Assuming results of different studies to be independent, this model simplifies to a univariate Bayesian model for dependent studies. An alternative model considered is $Y_j \sim \text{MVN}(\theta_j, \Sigma_j)$, $j = 1, \dots, p$, where Y_j and θ_j are

k -dimensional vectors of outcomes across the k studies. The variance–covariance matrix Σ_j has dimension equal to the number of studies, which can be large, and information may not be available to assist with estimation of the matrix elements. Moreover, the model is less able to adjust for estimate differences from studies reporting all outcomes and those reporting a subset of outcomes. The third proposed model is a Bayesian adaptation of the mixed model for multicenter trials that allow more than one summary statistic per outcome in each study.

A similar Bayesian meta-analysis model to analyze the same outcome measured at two times is extended by Abrams et al.^[42] to investigate potential associations between risk at baseline and relative risk. For an application presented to assess management of patients who have acute coronary syndrome in terms of an outcome (mortality) as measured at two follow-ups after a treatment was applied, a proportion of trials reported the outcome six months after treatment, and most reported it 30 days after treatment. Opinions from coronary care consultants were obtained regarding their beliefs on mortality at 30 days and six months after treatment, in an attempt to extend on the limited data available.

General Bayesian mixed model approaches for meta-analysis have been promoted and illustrated by DuMouchel, with particular focus on combining studies of interest to the pharmaceutical sciences.^[4]

Other Frameworks

The above hierarchical (frequentist random-effects and Bayesian) models are often described in a multilevel modeling (MLM) framework.^[27] Analysis is typically performed using restricted maximum likelihood estimation (MLE)^[43] or GLS regression as described above. MLMs in meta-analysis are described as comprising two stages: the within-study or measurement model that predicts effect sizes from each study (relating estimated effect sizes from each study to the true effect sizes) and the study-level model that predicts effects across studies. The model extends to multivariate meta-analysis using other outcomes such as correlations or summary effects such as odds ratios, and to studies with multiple treatments.^[27]

Becker^[29,44] describes methods of combining correlations. Inter-relationships among variables can be analyzed by fixed-effects or random-effects models. A set of linear models is derived from the correlation matrix that describes both direct and indirect relationships between outcomes and explanatory variables. Inferences are made on the coefficients of the resultant standardized regression equations.

The definition of “multivariate” can also be extended to include multiple endpoints from dose–response studies. In this case, each study provides a series of dose-specific relative risks compared to a common reference group. Again, fixed-effects and random-effects models can be constructed.^[45]

CONCLUSIONS

There are a range of methods to select from when dealing with a meta-analysis for multivariate data. It is important that relationships between outcomes be acknowledged either in the modeling procedure or in a sensitivity analysis with the intention to quantify the effect for the situation that it is excluded from the model. A number of factors will determine the method to apply including the number, importance of in addressing the objective of the meta-analysis, and degree of similarity in outcomes. Univariate meta-analysis methods can be used when few studies report multiple outcomes or when the multivariate component is not of importance. If the multivariate nature of the data is a major component of the meta-analysis, associated multivariate methods in meta-analysis that account for the dependence between outcomes should be adapted. Correlations between outcomes, which are typically not reported in studies, must be estimated or imputed from alternative sources. The corresponding multivariate method has advantages in terms of providing additional information about relevant outcomes by borrowing strength across effects both within and between studies. Decisions must additionally be made in the multivariate framework regarding identification of fixed and random effects, describing within- and between-study heterogeneity, and choosing between the frequentist or the more flexible Bayesian framework within which to model these features.

Noninferiority Trials: Type I Error Rates

Seung-Ho Kang

Department of Applied Statistics, Yonsei University, Seoul, South Korea

Abstract

The purpose of this entry is to help people avoid the ambiguity of type I error rates in non-inferiority trials that compare a new treatment to an active control without a placebo arm.

Keywords: Within-trial type I error; Across-trial type I error; Within-trial power; Across-trial power.

INTRODUCTION

Non-inferiority trials that compare a new treatment to an active control without a placebo arm are popular. These types of trials are mainly classified into two categories, depending on their objectives.^[1] In the first category, the objective is to compare the effectiveness of two treatments whose efficacy has already been proven in past trials. In the second category, the objective is to gain approval for a new treatment from a regulatory body by comparing the new treatment to an active control without a placebo arm for ethical reasons. This entry concentrates on the second objective.

REVIEW OF STATISTICAL METHODS FOR AN ANALYSIS OF NON-INFERIORITY CLINICAL TRIALS

Let $X_{T,i}$ and $X_{C,i}$ denote the continuous primary end points from the test treatment and the active control treatment, respectively, in the current non-inferiority clinical trial, with $i = 1, 2, \dots, n$. Let $X_{CH,i}$ and $X_{PH,i}$ represent the continuous primary end points from the active control treatment and placebo product, respectively, in the historical trial, with $i = 1, 2, \dots, n_H$. It is assumed that the sample sizes (n, n_H) are large enough to employ the Central Limit Theorem. It is also assumed that:

$$\begin{aligned} E(X_{T,i}) &= \mu_T, E(X_{C,i}) = \mu_C, \text{Var}(X_{T,i}) \\ &= \text{Var}(X_{C,i}) = \sigma^2 < \infty \end{aligned} \quad (1)$$

and

$$\begin{aligned} E(X_{CH,i}) &= \mu_{CH}, E(X_{PH,i}) = \mu_{PH}, \text{Var}(X_{CH,i}) \\ &= \text{Var}(X_{PH,i}) = \sigma_H^2 < \infty \end{aligned} \quad (2)$$

The Fixed-Margin Method (the Two Confidence Interval Method with a Fixed Margin)

Given that the two methods described in this section and the following section are both occasionally referred to as “the fixed-margin method;” we need different names here to distinguish the two methods presented in the two sections. In order to avoid confusion. We will refer to the fixed-margin method introduced in section and the following section as the two confidence interval (TCI) method with a fixed margin, as the non-inferiority margin is treated as a constant.^[2] This method is clearly described by Hung, Wang, and O'Neill.^[3]

Suppose that larger values of the primary end points lead to favorable outcomes. Then, hypotheses of the fixed-margin method (TCI with a fixed margin) are then expressed as follows:

$$H_{01} : \mu_T - \mu_C \leq -\delta \text{ vs } H_{A1} : \mu_T - \mu_C > -\delta \quad (3)$$

where $\delta(>0)$ is a non-inferiority margin. It is recommended that a non-inferiority margin is determined based on the statistical margin and clinical margin.^[4] The statistical margin is often determined as the 95% lower confidence limit for the active control effect from historical trials. Once the margin is determined, it is treated as a fixed constant, although a lower confidence limit may be involved with the determination of a non-inferiority margin.^[3] If the lower confidence limit is considered as a random variable, the hypotheses in Eq. 3 include a random variable, which violates the basic frequentist statistical principle that hypotheses must not have any random variables.^[5] Therefore, the variability of the historical data is not taken into account in this method.

If:

$$(\bar{X}_T - \bar{X}_C) - 1.96\hat{\sigma}_{TC} > -\delta \quad (4)$$

subsequently, we reject the null hypothesis H_{01} in Eq. 3 where $\hat{\sigma}_{TC}$ is an estimate of the standard error of $(\bar{X}_T - \bar{X}_C)$ and:

$$\bar{X}_T = \frac{1}{n} \sum_{i=1}^n X_{T,i}, \bar{X}_C = \frac{1}{n} \sum_{i=1}^n X_{C,i} \quad (5)$$

The Fixed-Margin Method (The Two Confidence Interval Method with a Random Margin)

The method introduced in this section is also sometimes called “the fixed-margin method.”^[6,7] In order to avoid confusion, we refer to the fixed-margin method in this section as the TCI method with a random margin, because the margin is treated as a random variable.^[2] Therefore, this method incorporates the uncertainty associated with the estimation of the non-inferiority margin.

One approach for defining a non-inferiority margin in TCI with a random margin is to make the margin preserve $100\lambda\%$ ($0 \leq \lambda \leq 1$) of the active control effect. Therefore, the hypotheses of interest are expressed as given by:

$$\begin{aligned} H_{02} : (\mu_T - \mu_{P,put}) / (\mu_C - \mu_{P,put}) &\leq \lambda \text{ versus} \\ H_{A2} : (\mu_T - \mu_{P,put}) / (\mu_C - \mu_{P,put}) &> \lambda \end{aligned} \quad (6)$$

where $\mu_{P,put}$ denotes the population mean of the putative placebo in the current non-inferiority trial. It is important to recognize that $\mu_{P,put}$ cannot be estimated because there is no placebo arm in the current non-inferiority trial. If we present the hypotheses in Eq. 6 in the form of the hypotheses in Eq. 3, the hypotheses of the TCI with a random margin are given by:

$$H_{03} : \mu_T - \mu_C \leq -\delta \text{ versus } H_{A3} : \mu_T - \mu_C > -\delta \quad (7)$$

where $\delta = (1 - \lambda)(\mu_C - \mu_{P,put})$ is the non-inferiority margin. The minimal requirement for approval of a new treatment from a regulatory agencies ($\mu_T > \mu_{P,put}$) is obtained from the alternative hypothesis H_{A3} when $\lambda = 0$. The superiority of a new treatment over the active control ($\mu_T > \mu_C$) is obtained when $\lambda = 1$. It is assumed that the effect size of the active control with respect to the placebo does not change from the historical trial to the current non-inferiority trial. This is known as the constancy assumption:

$$\mu_C - \mu_{P,put} = \mu_{C|H} - \mu_{P|H} \quad (8)$$

The non-inferiority margin δ is estimated with the estimate of $(\mu_{C|H} - \mu_{P|H})$ from the historical trials based on the constancy assumption. The lower limit of the 95% confidence interval of $(\mu_{C|H} - \mu_{P|H})$ is often chosen as a conservative estimate of $(\mu_C - \mu_{P,put})$. A meta-analysis is performed when there are several historical trials. The TCI with a random margin method then rejects the null hypothesis H_{03} , if:

$$(\bar{X}_T - \bar{X}_C) - 1.96\hat{\sigma}_{TC} > - (1 - \lambda)(\bar{X}_{C|H} - \bar{X}_{P|H} - 1.96\hat{\sigma}_{PC|H}) \quad (9)$$

where,

$$\bar{X}_{P|H} = \frac{1}{n_H} \sum_{i=1}^{n_H} X_{P|H,i}, \bar{X}_{C|H} = \frac{1}{n_H} \sum_{i=1}^{n_H} X_{C|H,i} \quad (10)$$

and $\hat{\sigma}_{PC|H}$ is the estimate of the standard error of $(\bar{X}_{C|H} - \bar{X}_{P|H})$.

The Synthesis Method

The synthesis method uses hypotheses which are identical to those of the TCI with a random margin in Eq. 6. Based on the constancy assumption in Eq. 8, the hypotheses in Eq. 6 can be rewritten as follows:

$$\begin{aligned} H_{04} : (\mu_T - \mu_C) &\leq (\lambda - 1)(\mu_{C|H} - \mu_{P|H}) \text{ versus} \\ H_{A4} : (\mu_T - \mu_C) &> (\lambda - 1)(\mu_{C|H} - \mu_{P|H}) \end{aligned} \quad (11)$$

Although the current non-inferiority trial and the historical trial are two different clinical trials conducted at different times and different protocols, the synthesis method treats both trials as if they came from the same randomized clinical trial with the same protocol. Therefore, the test statistic is given as follows:

$$T = \frac{(\bar{X}_T - \bar{X}_C) - (\lambda - 1)(\bar{X}_{C|H} - \bar{X}_{P|H})}{\sqrt{\hat{\sigma}_{TC}^2 + (\lambda - 1)^2 \hat{\sigma}_{PC|H}^2}} \quad (12)$$

If $T > 1.96$, the null hypothesis H_{04} in Eq. 11 is rejected. Although there may exist several placebo-controlled historical trials, for the sake of simplicity, we assume here that the historical trials are collectively a single placebo-controlled trial whose hypotheses and test statistics can be expressed as shown below:

$$H_{0,H} : \mu_{C|H} = \mu_{P|H} \quad T_H = \frac{(\bar{X}_{C|H} - \bar{X}_{P|H})}{\sqrt{\hat{\sigma}_{PC|H}^2}} \quad (13)$$

If $|T_H| > 1.96$, the null hypothesis $H_{0,H}$ in Eq. 13 was rejected.

Differences between the Three Methods

Only the data in the current non-inferiority trial is treated as random variables in the fixed-margin method (TCI with a fixed margin) in section “The Fixed Margin Method (the Two Confidence Interval Method with a Fixed Margin).” Although historical data can be used for the determination of the non-inferiority margin, these data are not regarded as random variables.

On the other hand, both data in the current non-inferiority trial and historical data are treated as random variables in

the fixed-margin method (TCI with a random margin) in section “The Fixed-Margin Method (the Two Confidence Interval Method with a Random Margin)” and in the synthesis method in section “The Synthesis Method.” Therefore, all data from the two trials are involved in statistical inference. It is very important to understand which data are treated as random variables and which data are involved in statistical inference, as this is directly related to which type I error rate should be evaluated and controlled.

There is asymptotic equivalence between TCI with random margin and the synthesis method, apart from the critical value. From Eq. 9, we have :

$$\begin{aligned} \bar{X}_T - \bar{X}_C - 1.96\hat{\sigma}_{TC} &> \\ &- (1-\lambda)(\bar{X}_{C|H} - \bar{X}_{P|H} - 1.96\hat{\sigma}_{PC|H}): \\ \Leftrightarrow (\bar{X}_T - \bar{X}_C) + (1-\lambda)(\bar{X}_{C|H} - \bar{X}_{P|H}) &> \\ 1.96[\hat{\sigma}_{TC} + (1-\lambda)\hat{\sigma}_{PC|H}] & \end{aligned} \quad (14)$$

$$\Leftrightarrow T > 1.96\hat{f} \quad (15)$$

where T is the test statistic in the synthesis method in Eq. 12 and $\hat{f} = \frac{\hat{\sigma}_{TC} + (1-\lambda)\hat{\sigma}_{PC|H}}{\sqrt{\hat{\sigma}_{TC}^2 + (1-\lambda)^2\hat{\sigma}_{PC|H}^2}}$.

Furthermore, we have:

$$T \xrightarrow{d} N(0,1) \text{ under } H_{04} \quad \hat{f} \xrightarrow{P} f = \frac{\sigma_{TC} + (1-\lambda)\sigma_{PC|H}}{\sqrt{\sigma_{TC}^2 + (1-\lambda)^2\sigma_{PC|H}^2}} \quad (16)$$

Hence, the TCI with a random margin is asymptotically equivalent to the synthesis method except that the cutoff value 1.96 is replaced with $1.96\hat{f}$. Note that the value of f is greater than 1, which shows that TCI with a random margin in section “The Fixed-Margin Method (the Two Confidence Interval Method With a Random Margin)” is more asymptotically conservative than the synthesis method in the section “The Synthesis Method.”

TYPE I ERROR RATES

The Within-Trial Type I Error Rate

The within-trial type I error rate is calculated with only random variables in the current non-inferiority trials. The non-inferiority margin obtained from the historical trial is considered as a fixed constant. Therefore, the within-trial type I error rate should be used for the fixed-margin method (TCI with a fixed margin) in section “The Fixed Margin Method (the Two Confidence Interval Method with a Fixed Margin).” The specific formula of the within-trial type I error rate for the hypotheses in Eq. 3 is given below:

$$P(\text{reject } H_{01} | H_{01}) = P\left(\frac{\bar{X}_T - \bar{X}_C + \delta}{\hat{\sigma}_{TC}} > 1.96 | H_{01}\right) \quad (17)$$

Here, $\hat{\sigma}_{TC}$ is an estimate of the standard error of $(\bar{X}_T - \bar{X}_C)$. From Eq. 17, it is clear that only the random variables $\bar{X}_T$ and $\bar{X}_C$ in the current non-inferiority trial are utilized in the calculation of the within-trial type I error rates. Within-trial type I error rates were studied by Brittain and Hu,^[8] Hilton,^[9] Sanchez and Chen,^[10] and Sheng and Kim,^[11] Hung et al.,^[1,3,12] Kang and Tsong,^[13] and Wang and Kang^[2] discussed the characteristics of the within-trial type I error rate.

It is necessary to understand the following characteristics of the within-trial type I error rate.

1. If we want to conduct simulation studies that evaluate the within-trial type I error rate, random numbers should be generated only from the current non-inferiority trials. Although the non-inferiority margin can be calculated from the historical trials, such a procedure is not reflected in the simulation. Therefore, we do not need to generate random numbers from the historical trials.
2. As a minimum requirement for the approval of a test treatment by a regulatory body, the non-inferiority trial should demonstrate that the test treatment would be more effective than a placebo, if a placebo was present in the trial.^[4] Accordingly, the hypotheses of such a minimum requirement are expressed as follows:

$$H_{05} : \mu_T \leq \mu_{P,put} \text{ versus } H_{A5} : \mu_T > \mu_{P,put} \quad (18)$$

Note that the hypotheses in Eq. 18 are actually untestable, as there is no placebo group in the current non-inferiority trial. The within-trial type I error rate does not evaluate the type I error rate associated with the hypotheses in Eq. 18, instead assessing only the type I error rate associated with the hypotheses in Eq. 3.

3. If $H_{A1} : \mu_T - \mu_C > -\delta$ in Eq. 3 is accepted and the non-inferiority margin δ is chosen such that:

$$\mu_{C|H} - \mu_{P|H} \geq \delta \quad (19)$$

based on indirect inference, the constancy assumption in Eq. 8 leads to the conclusion that the test treatment is more effective than a putative placebo.

$$\mu_T - \mu_C > -\delta \geq -(\mu_{C|H} - \mu_{P|H}) \text{ from (3) and (19)}$$

$$\Rightarrow (\mu_T - \mu_C) + (\mu_{C|H} - \mu_{P|H}) > 0$$

$$\Leftrightarrow (\mu_T - \mu_C) + (\mu_C - \mu_{P,put}) > 0$$

from constancy assumption in (8)

$$\Leftrightarrow \mu_T - \mu_{P,put} > 0 \quad (20)$$

However, because this conclusion does not have statistical inference, we cannot assess the type I error rate associated with the conclusion from Eq. 20 with

the within-trial type I error rate. Hung, Wang, and O'Neill^[3] write, “This within-trial type I error rate of the non-inferiority trial cannot help quantify the error rate associated with such an indirect inference.”

4. The within-trial type I error rate represents the type I error rate of the falsely concluded non-inferiority in Eq. 3 with the fixed margin when the non-inferiority trial is repeated infinitely many times with an identical fixed margin.^[14] The within-trial type I error rate appears to be the most familiar type I error rate to the statisticians and clinicians involved in clinical trials.
5. When the primary end point is continuous, the well-known sample size calculation formula for the two-arm non-inferiority trial is expressed as shown below:^[15]

$$n_1 = kn_2, n_2 = \frac{(z_{\alpha/2} + z_{\beta})^2 \sigma^2 (1 + 1/k)}{(|\mu_T - \mu_C| - \delta)^2} \quad (21)$$

This formula is obtained from the within-trial power because it considers only the data in the current non-inferiority trial as random variables. Therefore, this formula produces appropriate sample sizes when the fixed-margin method (TCI with a fixed margin) in the section “The Fixed Margin Method (the Two Confidence Interval Method with a Fixed Margin)” is used. However, if the fixed-margin method (TCI with a random margin) in the section “The Fixed-Margin Method (the Two Confidence Interval Method with a Random Margin)” is employed, the formula given in Eq. 21 should not be used. Instead, another formula based on the across-trial power should be employed. The point (9) of section “The unconditional Across-Trial Type I Error Rate” will address this issue.

6. Although the constancy assumption does not hold, this does not affect the within-trial type I error rate, as it assesses only the type I error rate related to the hypotheses in Eq. 3 for a given fixed margin $\delta > 0$, regardless of how the margin is chosen. A violation of the constancy assumption can affect the conclusion in Eq. 20, but the within-trial type I error rate cannot assess the degree to which it does statistically.
7. Hung, Wang, and O'Neill^[14] refer to the within-trial type I error rate as “the conditional type I error rate.” However, this wording is slightly misleading. It is important to note that the within-trial type I error rate is an “unconditional” probability, not a “conditional” probability, because the non-inferiority margin is treated as a constant and not as a random variable.
8. When one studies some of the statistical properties of the fixed-margin method (TCI with a fixed margin) in the section “The Fixed Margin Method (the Two Confidence Interval Method with a Fixed Margin),” it is also possible to study only the within-trial type I error rate and the within-trial power but not the across-trial type I error rate and across-trial power.

The Unconditional Across-Trial Type I Error Rate

In this section, we describe the unconditional across-trial type I error rate of the synthesis method. Due to the existence of asymptotic equivalence between the synthesis method and the fixed-margin method (TCI with a random margin), as shown in the section “Differences between the Three Methods,” a similar description can be obtained for the fixed-margin method (TCI with a random margin).

The unconditional across-trial type I error rate of the synthesis method is given by:

$$P(T \geq 1.96 | H_{04}) = \int P(T \geq 1.96 | T_H = t_H, H_{04}) w_{T_H}(t_H) dt_H \quad (22)$$

where T is determined in Eq. (12) and $w_{T_H}(t_H)$ is the probability density function of T_H . Eq. 22 can be derived from the following well-known properties of a conditional expectation.

$$E[A] = E_{T_H}[E[A | T_H]], A = I_{[T \geq 1.96]} \quad (23)$$

This equation shows that the unconditional across-trial type I error rate is a weighted average of the conditional across-trial type I error rates. The unconditional across-trial type I error rate was evaluated by Kang and Ryu,^[16] Odem-Davis and Fleming,^[17] Snapinn and Jiang,^[6] Soon et al.,^[7] Wang, Hung, and Tsong,^[18] Wang and Hung,^[19] and Wang and Kang.^[2]

The unconditional across-trial type I error rate has the following characteristics:

1. The unconditional across-trial type I error rate is appropriate for the synthesis method and the fixed-margin method (TCI with a random margin) because both data in the current non-inferiority trial and data in the historical trial are treated as random variables. If we want to conduct simulation studies that evaluate the unconditional across-trial type I error rate, random numbers should be generated from both current non-inferiority trial and historical trial. If the non-inferiority margin is chosen from the historical data, this procedure should be reflected in simulation studies.
2. The paradigm of the within-trial type I error rate differs from that of the unconditional across-trial type I error rate, and they are as a result not comparable.^[3] Therefore, the values of these two type I errors should not be compared.
3. The fixed-margin method (TCI with a random margin) is more conservative than the synthesis method in terms of the unconditional across-trial type I error rate.^[4,18] When one asserts that a particular method is conservative, one should state clearly the type of type I error in relation to which this is so.

4. When $\lambda = 0$ in Eq. 6, we can assess the unconditional across-trial type I error rate for the hypotheses in Eq. 18, while we cannot evaluate the within-trial type I error rate. This is advantageous, as the hypotheses in Eq. 18 represent the minimal requirement for the approval of the test treatment.
5. The current non-inferiority trial and the historical trial are in fact different studies conducted with different protocols at different times. Furthermore, randomization and blinding are not used. However, in the evaluation of the unconditional across-trial type I error rate, all four arms (the test treatment and active control in this study and the active control and placebo in the historical study) are treated as if they come from the same clinical trial, which may cause substantial bias.^[20]
6. If there are several historical trials, there is some concern over the occurrence of selection and publication bias.^[20] These types of bias can affect the unconditional across-trial type I error rate. Hung and Wang^[21] pointed out that subjective judgment when selecting the relevant historical trials among several trials and the construction of a meta-analytic estimate of the control effect in multiple ways may produce multiplicity issues and inflate the family-wise unconditional across-trial type I error rate because the historical data are treated as random variables.
7. Even before we begin the non-inferiority trial, the historical trial is already finished and the historical data have already been observed. However, the unconditional across-trial type I error rate is calculated by incorporating all possible (even unobserved) values of historical trial data, which may not make sense.^[13] The unconditional across-trial type I error rate represents the type I error rate of the falsely concluded non-inferiority in Eq. 7 or 11 when both the non-inferiority trial and the historical trial are repeated infinitely.^[14] However, given that the historical trial has already finished, it may be unreasonable to assume that it is repeated infinitely.
8. Because the historical data are treated as random variables and given that T and T_H share the same historical data, the following correlation exists between them.^[2,13,16]

$$\rho = \frac{-(\lambda - 1)\sigma_H^2}{\sqrt{\sigma_H^2[\sigma^2 + (\lambda - 1)^2\sigma_H^2]}} = \frac{-(\lambda - 1)}{\sqrt{r^2 + (\lambda - 1)^2}}, \quad (24)$$

$$r^2 = \sigma^2 / \sigma_H^2$$

In other words, the correlation affects the extent to which T is significant; therefore, the appropriate type I error rate should depend on the correlation. However, the unconditional across-trial type I error rate does not consider this correlation and has an identical value regardless of the value of the correlation.^[2,13,16]

This arises because all possible (even unobserved) values of the historical trial data are incorporated into the calculation of the unconditional across-trial type I error rate. On the other hand, the conditional across-trial type I error rate considers only the observed value of the historical data; hence, it has a desirable property. This will be discussed in detail in point (2) of the section “The Conditional Across-Trial Type I Error Rate.”

9. If the unconditional across-trial type I error rate is employed, the formula given in Eq. 21 should not be used, as it is based on the within-trial power. Rothman, Wiens, and Chan^[22] provide a sample size calculation method based on the unconditional across-trial power.
10. Suppose that in the fixed-margin method (TCI with a fixed margin) in the section “The Fixed Margin Method (the Two Confidence Interval Method with a Fixed Margin),” the non-inferiority margin was selected as a fraction of the lower confidence limit of the effect size of the active control in the historical trial.

$$\delta = (1 - \lambda)(\bar{X}_{CH} - \bar{X}_{PH} - 1.96\hat{\sigma}_{PC|H}) \quad (25)$$

This margin is treated as a fixed constant once it is determined. Whenever the null hypothesis H_{01} is rejected by the fixed-margin method (TCI with a fixed margin) in the section “The Fixed Margin Method (the Two Confidence Interval Method with a Fixed Margin),” the null hypothesis H_{03} is also rejected by the fixed-margin method (TCI with a random margin) in the section “The Fixed-Margin Method (the Two Confidence Interval Method with a Random Margin)” and vice versa. This most likely is why the names of these two methods are identical. However, these two methods should assess different type I error rates because they employ different paradigms. The fixed-margin method (TCI with a fixed margin) in the section “The Fixed Margin Method (the Two Confidence Interval Method with a Fixed Margin)” should assess the within-trial type I error rate, while the fixed-margin method (TCI with a random margin) in the section “The Fixed-Margin Method (the Two Confidence Interval Method with a Random Margin)” should evaluate the (either unconditional or conditional) across-trial type I error rate.

The Conditional Across-Trial Type I Error Rate

The conditional across-trial type I error rate is defined as follows:

$$P(T \geq 1.96 | T_H = t_H, H_{03} \text{ or } H_{04}) \quad (26)$$

When the across-trial type I error rate is assessed, the historical data are treated as random variables. However, because the historical data have already been observed, a conditional probability rather than an unconditional probability may be more appropriate as a type I error rate. This is the main motivation of the conditional across-trial type I error rate.^[13]

The conditional across-trial type I error rate has the following characteristics.

1. The conditional across-trial type I error rate incorporates only the observed values of the historical data, whereas the unconditional across-trial type I error rate takes into account all possible (even unobserved) values of the historical trial data. Therefore, the conditional across-trial type I error rate appears to be more suitable than the unconditional across-trial type I error rate.^[13]

The conditional across-trial type I error rate is truly a conditional probability given that the observed value of T_H is equal to t_H . The conditional across-trial type I error rate is the type I error rate of the falsely concluded non-inferiority in Eq. 7 or 11 with an identical fixed value of T_H when the only non-inferiority trial (not historical trial) is repeated infinitely with the same fixed value of the random variable margin. This idea is appealing because the historical trial was finished and cannot be repeated.^[13]

2. With the asymptotic property of T given T_H , the conditional across-trial type I error rate is given by:^[13]

$$P(T \geq 1.96 \mid T_H = t_H, H_{04}) \rightarrow 1 - \Phi\left(\frac{1.96 - \rho t_H}{\sqrt{1 - \rho^2}}\right) \text{ as } n \rightarrow \infty \quad (27)$$

where Φ is the cumulative distribution function of the standard normal distribution. From the formula given in Eq. 27, we see that the conditional across-trial type I error rate depends on the correlation coefficient ρ between T and T_H . As a result, the conditional across-trial type I error rate appears to be more appropriate than the unconditional across-trial type I error rate due to the reason described in point (8) of the section “The Unconditional Across-Trial Type I Error Rate.” A major problem of the conditional across-trial type I error rate is that it depends on the unknown nuisance parameter $(\mu_{CH} - \mu_{PH})$.^[13]

CONCLUSION

Based on the following reasons, the within-trial type I error rate should be controlled such that it remains under the nominal level in order to receive approval for a new

treatment from regulatory agencies in two-arm non-inferiority trials.

1. In Statistics 101: In the “Introduction,” we learned the frequentist statistical principle, which states that hypotheses should be established prior to conducting an experiment. Hypotheses consist of unknown parameters and known constants. Information such as historical data can only be reflected in the constants in the hypotheses and/or in the form of the hypotheses. The hypotheses are not allowed to have any random variables from historical data. Therefore, as long as we observe the frequentist statistical principle, the non-inferiority margin should be treated as a fixed constant. A problem with this method is that it ignores the variability of the historical data when calculating the non-inferiority margin. However, this is the price that we should pay if we follow the frequentist statistical principle.
2. As described in point (5) of the section “The Unconditional Across-Trial Type I Error Rate,” to calculate the across-trial type I error rate, both current non-inferiority trial and historical trial are treated as an identical clinical trial that was conducted with identical protocols at the same time. However, this is not true. Ignoring this truth may produce considerable bias, which cannot be quantified.
3. Treating historical data as random variables during the calculation of the across-trial type I error rate may cause a serious problem. Questions of which historical trials are selected and how to use these historical trials may arise when there are several historical trials. Selection and publication biases may occur, as described in point (6) of section “The Unconditional Across-Trial Type I Error Rate,”^[20] which may affect the across-trial type I error rate. The family-wise across-trial type I error rate may also be inflated due to the subjective selection of historical trials and the multiple methods of calculating the meta-analytic estimate of the active control effect.^[21]
4. The sample size formula given in Eq. 21 has been widely employed in non-inferiority trials. Because the formula is based on the within-trial power, it is the within-trial type I error rate, which should be held under the nominal level. If one controls the across-trial type I error rate, the sample size should also be computed based on the across-trial power.
5. A disadvantage of the unconditional across-trial type I error rate is that it does not take into account the correlation between T and T_H , as described in point (8) of section “The Unconditional Across-Trial Type I Error Rate.” Hence, the unconditional across-trial type I error rate exceeds the nominal level as the correlation increases.^[13] A problem with the conditional across-trial type I error rate is that it cannot be calculated owing to the unknown nuisance parameter.

Abstract

Clinical Trial Simulations for Later Development Phases Clinical trial simulation plays an important role in drug development and, in recent years, it has become increasingly popular in the pharmaceutical industry. The focus of this entry is the simulation for adaptive trial designs, which will be defined in detail through several statistical examples.

INTRODUCTION

Non-parametric regression is a fundamental tool in data analysis and provides an effective and simple way of finding data structure. The goal is to recover an unknown function based on sampled data that are contaminated with noise. Hess et al.^[1] have compared several non-parametric methods for estimating hazard functions. Parametric regression models (e.g., linear regression) have finite number of parameters to be estimated, whereas non-parametric models assume only very general assumptions about the unknown function such as that it belongs to a certain class of smooth functions. When estimating r , “smooth” means typically that r is twice continuously differentiable, so there are infinitely many parameters in a non-parametric model.

Given data points (x_i, y_i) where y_i is the observed response at x_i , $i = 1, \dots, n$, we want to study the relationship between x and y . The relationship can be written in general as

$$y_i = r(x_i) + \sigma \varepsilon_i$$

for some unknown function r . The random errors ε_i are assumed to be independently distributed with mean $E(\varepsilon_i) = 0$ and variance $V(\varepsilon_i) = 1$. For random designs where x_i are random variables, the function r is the expectation $r(x) = E(y|x)$. Usually it is assumed that ε_i and x_i are independent. The function r has to be estimated at each x , without the help of a parametric model which specifies qualitatively the relationship between x and y .

Non-parametric regression has been a very active field of statistics, and many methods have been proposed for estimating the function r . The commonly used methods (kernel estimators, smoothing splines, local polynomials, linear wavelet shrinkage) are linear methods in the sense that they are weighted averages of the observed responses

$$\hat{r}(x) = \sum_{i=1}^n w_i(x|x_1, \dots, x_n, b) y_i \quad (1)$$

where w_i are weights depending on design data points x_i , $i = 1, \dots, n$, a smoothing parameter b (“bandwidth”) indicating the extent of smoothing, and the point x at which the function is being estimated. A focal point in these estimators is the selection of the smoothing parameter b , and many methods (global, local, data driven) have been proposed for this purpose. The selection of b depends on the noise level σ and the smoothness of r (see below).

We will describe linear estimators in the section “Linear Estimators.” Spatially adapted wavelet shrinkage/threshold methods, which are similar to the kernel estimators with locally determined smoothing parameters, will also be described there. Analyzing a sample of similar curves (e.g., growth curves, dose-response curves) will be discussed in the section “Analyzing Sample of Curves.” An iterative algorithm based on kernel smoothing and dynamic time warping will be applied to analyze the Zurich growth data in the section “Application to Growth Data” and brain potentials in the section “Application to Brain Potentials.” Multivariate regression and density estimation will be briefly discussed in the section “Kernel Density Estimation and Multivariate Regression.” Some software resources are mentioned in the section “Software,” which is followed by a short conclusion.

LINEAR ESTIMATORS

Without loss of generality we assume that the design points satisfy $0 \leq x_1 < \dots < x_n \leq 1$.

Kernel Estimators

The weights w_i in (1) are derived from a kernel function K , which is usually chosen to satisfy $K(x) = K(-x)$ and to have compact support. Nadaraya^[2] and Watson^[3] proposed the weights

$$w_i(x|x_1, \dots, x_n, b) = K\left(\frac{x-x_i}{b}\right) / \sum_{j=1}^n K\left(\frac{x-x_j}{b}\right).$$

Convolution type weights were proposed by Gasser and Muller^[4,5] as

$$w_i(x|x_1, \dots, x_n, b) = \frac{1}{b} \int_{s_{i-1}}^{s_i} K\left(\frac{x-u}{b}\right) du$$

where $s_i = (x_i + x_{i+1})/2$, $s_0 = 0$, and $s_{n+1} = 1$.

The kernel and the smoothing parameters have to be selected in order to apply the estimator in Eq. (1). The estimator $\hat{r}$ is as smooth as the kernel K . The kernel has to satisfy certain conditions such as $\int K(x)dx=1$ for estimating the function r and $\int K(x)xdx=0$ together with $\int K(x)xdx=-1$ for estimating the first order derivative of r .^[6] For estimating the function r , the Epanechnikov kernel $K(x) = 3/[4(1-x^2)_+]$ is optimal in the sense that it minimizes the mean square error (MSE), which is the sum of variance and square of the bias.⁶ The derivatives of the unknown function r can be estimated by a similar weighted average with specially constructed kernels. Optimal kernels for estimating derivatives and special boundary kernels were also presented in Gasser et al.^[6] The boundary region consists of the intervals $(0, b)$ and $(1-b, 1)$ and a naive application of the kernels for the interior leads there to bias problems, as they are no longer symmetric in these regions.

The smoothing parameter b determines the extent of smoothing. Because K has compact support, a small b means very few data points are used in the weighted average in Eq. (1) and therefore little smoothing is done. Globally selected smoothing parameter does not depend on the location where the function is estimated. For a smooth function without peaks and sharp changes, a globally selected smoothing parameter is appropriate. Locally selected smoothing parameter adapts to the fine structure of the unknown function r . Local smoothing parameter is larger where r is flat and smaller where r has peaks. The optimal parameter, which minimizes the asymptotic MSE, is given by^[7]

$$\text{Local: } b(x) = \left(\frac{\sigma^2}{cn r^{(2)}(x)^2} \right)^{1/5}$$

$$\text{Global: } b = \left(\frac{\sigma^2}{cn \int r^{(2)}(x)^2 dx} \right)^{1/5}$$

The constant c depends only on the kernel and $r^{(2)}$ is the second order derivative of r . These formulae depend on two parameters σ and $r^{(2)}$ which are unknown. Gasser et al.^[8] proposed a simple estimator of σ and Brockmann et al.^[7] proposed a “plug-in” method for estimating the optimal smoothing parameter. The plug-in method estimates $r^{(2)}$

first from data with oversmoothing. Wang and Gasser^[9] discussed the best relative rate for estimating the locally optimal bandwidth. A popular alternative for bandwidth selection is cross-validation (and related methods): a disadvantage is that cross-validation is more variable in theory and practice, an advantage is that it is generally applicable and relatively simple to implement.

Smoothing Splines

A smoothing spline is the solution to the penalized regression problem $\min_r S_b(r)$ where

$$S_b(r) = \sum_{i=1}^n (y_i - r(x_i))^2 + b \int_0^1 [r^{(2)}(x)]^2 dx.$$

Here b is a roughness penalty analogous to the bandwidth of the kernel estimator and $r^{(2)}$ is the second order derivative of the regression function. Without penalty ($b=0$), solving the minimization problem results in interpolating the data. With heavy penalty ($b \rightarrow \infty$), the solution approaches the least square linear fit. For a given smoothing parameter $0 < b < \infty$, the resulting estimator $\hat{r}$ is a natural cubic spline (piecewise cubic polynomial with continuous second order derivative) with knots at $x_1, \dots, x_n$.^[10] Silverman^[11] expresses smoothing spline as a kernel estimator with locally adaptive smoothing parameter asymptotically and took advantage of the explicit formula of kernel estimators in studying asymptotic properties of smoothing splines. Kelly and Rice^[12] propose restricted smoothing splines for monotone regression functions such as dose-response functions and growth curves. One could use a high order penalty term $\int_0^1 [r^{(m)}(x)]^2 dx$ to obtain a spline estimator that has $m-1$ absolutely continuous derivatives $r^{(p)}$, $p=1, \dots, m-1$, and bounded $r^{(m)}$.

The smoothing splines are defined implicitly via a minimization problem and many methods have been proposed for computing smoothing splines. One often-used method is to use a set of basis functions known as *B-splines* which are defined by the recurrence formula

$$B_{j,k}(x) = \frac{x-x_j}{x_{j+k-1}-x_j} B_{j,k-1}(x) + \frac{x_{j+k}-x}{x_{j+k}-x_j} B_{j+1,k-1}(x), k \geq 2$$

with $B_{j,1}(x) = 1$ for $x_j < x < x_{j+1}$.^[13] The smoothing cubic spline can be written as a linear combination of the cubic *B-splines* ($k=4$) as

$$r(x) = \sum_j \gamma_j B_j(x)$$

which leads to $(r(x_1), \dots, r(x_n))' = B\gamma$ with $B_j = B_j(x_i)$. Solve the minimization problem to get the coefficients

$$\hat{\gamma} = (B'B + bM)^{-1} B'\gamma, \text{ with } M_{ij} = \int_0^1 B_i^{(2)}(x) B_j^{(2)}(x) dx.$$

The *B-splines* are almost orthogonal so $B'B$ is almost diagonal, which makes the calculation fast.

Cross-validation can be applied to select the penalty parameter b from data to minimize the MSE.

Local Polynomials

The local polynomial estimator $\hat{r}(x)$ is obtained by locally weighted polynomial regression to minimize the weighted sum of squared residuals

$$\min_{a(x), b_1(x), \dots, b_k(x)} \sum_{i=1}^n K\left(\frac{x-x_i}{b}\right) [y_i - a(x) - b_1(x) \times (x-x_i) - \dots - b_k(x)(x-x_i)^k]^2.$$

Here K is a kernel and b a smoothing parameter as in kernel estimators. This leads to the estimator $\hat{r}(x) = a(x)$. Local linear fit ($k = 1$) has been used most frequently and the weights are

$$w_i(x|x_1, \dots, x_n, b) = g_i(x|x_1, \dots, x_n, b) / \sum g_j(x|x_1, \dots, x_n, b)$$

where

$$g_i(x|x_1, \dots, x_n, b) = K\left(\frac{x-x_i}{b}\right) (s_2(x|x_1, \dots, x_n, b) - (x-x_i) \times s_1(x|x_1, \dots, x_n, b))$$

$$s_p(x|x_1, \dots, x_n, b) = \sum_{j=1}^n K\left(\frac{x-x_j}{b}\right) (x-x_j)^p, \dots, p = 1, 2.$$

Local polynomials automatically adjust to the boundary, and in general the bias of local polynomial estimator declines and the variance increases with the order of the polynomial. Fan^[14] proves minimax properties of local polynomial estimators.

Similar to kernel estimators, a kernel and a smoothing parameter have to be selected before applying local polynomials for non-parametric regression. The Epanechnikov kernel is optimal over all non-negative symmetric functions.^[15] Cross-validation and plug-in methods can be applied to select the smoothing parameter. Seifert and Gasser^[16] have studied the variance properties of local polynomial fitting and proposed modifications to control variability when the design is sparse.

Fig. 1 illustrates the effect of smoothing parameter. This figure is produced using SAS procedure LOESS with local linear fitting. The globally optimal smoothing parameter, $b = 0.135$, is computed by the LOESS procedure. With undersmoothing ($b = 0.05$), noise is not removed. With oversmoothing ($b = 0.3$), detailed features are lost.

Wavelet Estimators

Smoothing or denoising can also be carried out in the frequency domain such as Fourier analysis. Fourier transform gives the spectral content of a signal, but it gives no information regarding where in time those spectral components appear. Therefore it is not suitable for non-stationary signal analysis. Wavelet transform provides time and frequency information simultaneously, hence giving a time frequency representation of the signal.

Fig. 1 Illustration of the effect of smoothing parameter. Dashed line is the true function and solid line is smoothed function (estimate). $b = 0$: data plot (no smoothing); $b = 0.05$: undersmoothing; $b = 0.135$: optimal smoothing parameter chosen by SAS procedure LOESS; $b = 0.3$: oversmoothing

Wavelets refer to a set of orthonormal basis functions generated by dilation and translation of a compactly supported scaling function (or father wavelet), ϕ , and a mother wavelet, ψ . A variety of different wavelet families now exist that combine compact support with various degrees of smoothness and numbers of vanishing moments, see Daubechies.^[17] Many types of functions can be sparsely and uniquely represented in terms of a wavelet series. Let

$$\phi_{jk}(x) = 2^{j/2} \phi(2^j x - k), \psi_{jk}(x) = 2^{j/2} \psi(2^j x - k), x \in [0, 1].$$

Then for any $j_0 \geq 0$,

$$\{\phi_{j_0 k}, k = 0, 1, \dots, 2^{j_0} - 1; \psi_{jk}, j \geq j_0, k = 0, 1, \dots, 2^j - 1\}$$

is an orthonormal basis of $L^2([0, 1])$. The basis with $\phi(x) = 1, x \in [0, 1]$, and $\psi(x) = 1, x \in [0, 1/2]$ and $\psi(x) = -1, x \in [1/2, 1]$, is the Haar wavelet family.

For any function $r \in L^2([0, 1])$, it can be represented as

$$r(x) = \sum_{k=0}^{2^{j_0}-1} \langle r, \phi_{j_0 k} \rangle \phi_{j_0 k}(x) + \sum_{j=j_0}^{\infty} \sum_{k=0}^{2^j-1} \langle r, \psi_{jk} \rangle \psi_{jk}(x).$$

The first term is the trend at scaling level j_0 and the second term is the sum of the fluctuation terms.^[18]

In non-parametric regression applications, the function is discretely sampled $R = (r(x_1), \dots, r(x_n))'$. If $n = 2^J$ for some positive integer J and $\{x_i\}$ are equally spaced, fast algorithm using filter banks exists^[19] for implementing the discrete wavelet transform (DWT) to calculate wavelet coefficients $\alpha_{j_0 k} = \langle r, \phi_{j_0 k} \rangle, k = 0, 1, \dots, 2^{j_0}-1$, and $\beta_{jk} = \langle r, \psi_{jk} \rangle, j = j_0, \dots, J-1; k = 0, 1, \dots, 2^j-1$. Note that DWT calculates only n wavelet coefficients. If these coefficients are known, then inverse discrete wavelet transform (IDWT) can be used to calculate the functional values at $\{x_i\}$ using n wavelets.

The wavelet coefficients calculated from noisy data $\{y_i\}$ can be represented as

$$\hat{\alpha}_{j_0 k} = \alpha_{j_0 k} + \sigma \tau_{j_0 k}, \hat{\beta}_{jk} = \beta_{jk} + \sigma \tau_{jk}.$$

Because the wavelets form an orthonormal basis of $L^2([0, 1])$, the transformed noise τ_{jk} are also independently distributed with mean $E(\tau_{jk}) = 0$ and variance $V(\tau_{jk}) = 1$. Wavelet methods are designed to estimate the true wavelet coefficients $\{\alpha_{j_0 k}, \beta_{jk}\}$ from the noisy ones $\{\hat{\alpha}_{j_0 k}, \hat{\beta}_{jk}\}$ and use IDWT to recover the true function.

For regression and denoising, two classes of wavelet estimates are often used. One is linear wavelet shrinkage which estimates the trend term coefficient $\alpha_{j_0 k}$ by $\hat{\alpha}_{j_0 k}$ and the fluctuation term coefficients β_{jk} by shrinking $\hat{\beta}_{jk}$ towards 0: $\tilde{\beta}_{jk} = s(j, b) \hat{\beta}_{jk}$ with $0 < s(j, b) < 1$. The shrinking factor $s(j, b)$ depends on a smoothing parameter b and possibly on the scaling level j . The smoothing

parameter depends on the estimated noise parameter σ . The other class is nonlinear wavelet thresholding which also estimates the trend term coefficient $\alpha_{j_0 k}$ by $\hat{\alpha}_{j_0 k}$, but it estimates the fluctuation term coefficients β_{jk} by thresholding $\tilde{\beta}_{jk} : \tilde{\beta}_{jk} = I(|\hat{\beta}_{jk}| > t(j, b)) \hat{\beta}_{jk}$ where the threshold $t(j, b)$ depends on a smoothing parameter b and possibly on the scaling level j . Antoniadis et al.^[20] have summarized various methods for selecting $s(j, b)$ and $t(j, b)$, and they selected the trend level j_0 as $j_0(n) = \log_2(\log(n)) + 1$ based on asymptotic considerations. Donoho and Johnstone^[21] have proposed an estimate of the noise level σ based on the wavelet coefficients given by

$$\hat{\sigma} = \frac{\text{median}(|\hat{\beta}_{j-1, k}| : k = 0, 1, \dots, 2^{j-1} - 1)}{0.6745}$$

ANALYZING SAMPLE OF CURVES

Many practical applications involve a sample of curves, or functional data. Examples are dose-response relationships from a group of subjects in early phase clinical trials, growth curves of children from birth to adulthood, speech signals, and brain potentials recorded from many channels and from many subjects. Such data can be modeled in the form

$$y_{ij} = r_i(x_{ij}) + \sigma \epsilon_{ij}, \quad j = 1, 2, \dots, n_i, \quad i = 1, 2, \dots, I.$$

There are I curves and curve i is sampled at n_i points.

Each curve can be estimated with the methods described in the section "Linear Estimators." Gasser et al.^[22] has suggested using the same smoothing parameter for all curves. They proposed to use the average of the optimal smoothing parameters derived for each individual curves.

The curves are similar in shape because these curves represent similar relationship between $\{x_{ij}\}$ and $\{y_{ij}\}$, yet the curves are different in characteristics (e.g., location and magnitude of peaks) due to inter-individual variations. Many methods such as principal component analysis deal with variations in amplitude while ignoring dynamic variations such as the timing of the features. There are sensitive and insensitive subjects in dose-response studies, children with earlier and later pubertal spurts, people speaking slowly or quickly, and subjects with different responses to stimulus when recording brain potentials. The aim is to model both similarity and individual variations, in particular when estimating a mean curve.

Many ideas and techniques for such data, including linear regression, principal components analysis, linear modeling, and canonical correlation analysis, as well as specifically functional techniques such as curve registration and principal differential analysis, are discussed in Ramsay and Silverman.²³ The following sections present several semiparametric and non-parametric methods for structural analysis of curves.

Shape-Invariant Modeling

The one-component shape-invariant model (SIM) is a semi-parametric model with a common “shape function” for all curves.^[22]

$$r_i(x_{ij}) = a_i s\left(\frac{x_{ij} - b_i}{c_i}\right) + d_i$$

where a_i , b_i , c_i , and d_i are individual parameters. Shape function and individual parameters have to be estimated from data. The Gompertz model of $s(x) = \exp[-\exp(-x)]$ is a parametric version of the SIM.

A sophisticated algorithm for estimating the shape function and individual parameters is sketched in Gasser et al.^[22] The algorithm starts from an approximate shape function (e.g., logistic function). Then individual parameters are estimated from data using the approximate shape function and nonlinear least squares. With the shape function and individual parameters at hand, the estimated curves can be calculated from the SIM model. An update for the shape function is then derived by fitting the residuals with smoothing or regression splines. This procedure is repeated until convergence.

Structural Analysis

Landmark-based methods are used in signal and image registrations.^[24,25] Landmarks are features of images. For curves, landmarks could be peaks of curves and their derivatives. Kneip and Gasser^[26] have proposed a landmark method to construct a mean curve of the sample curves. They used the term “structural average curve” because it was applied to growth curve analysis. The structural average curve can be an estimate of the shape function of the SIM model.

The structural averaging proceeds as follows:

- i. Estimates of individual curves and their first- and second-order derivatives are obtained with Kernel smoothing: $\hat{r}_i, \hat{r}'_i, \hat{r}''_i$.
- ii. Individual structural points are identified from $\hat{r}_i, \hat{r}'$, and/or $\hat{r}''$. Roughly speaking, structural points (called “landmarks” in shape analysis) are features that are common to all or most curves.
- iii. Shift functions $\hat{u}_i$ are constructed from the locations of the structural points such that individual structural points are shifted to the respective average location. In between, smooth monotonic interpolation is used.
- iv. A structural average $\hat{r}_0$ (in contrast to a cross-sectional average) is obtained by averaging aligned (smoothed) curves:

$$\hat{r}_0(x) = \sum_{i=1}^I \hat{r}_i(\hat{u}_i(x)) / I$$

Step (ii) sounds simple but it is rather delicate. It is not easy to define structural points that are common to most curves and to determine them unequivocally from noisy data, such that they have an equivalent meaning. Structural points could be defined based on the applications. For evoked brain potentials, the structural points might be P100, N100, P200, N200, and P300 (the positive and negative peaks occurring at about 100, 200, and 300 milliseconds after applying a stimulus). For general curve analysis, the structural points can be simply the peaks of $\hat{r}_i, \hat{r}'$, and $\hat{r}''$, which are common to most of the curves.

Step (iii) eliminates the dynamic variations among individuals by aligning the features across individuals. Once the features are identified in step (ii), this is a simple procedure.

Step (iv) is the average of the aligned curves.

Because of the averaging in step (iv), the average curve is much smoother than the smoothed individual curves and has little variation. Therefore, it is a good estimate of the shape function. Kneip and Gasser^[26] have shown that the structural average is closer to the underlying growth model than the mean of individually determined peak velocity of the pubertal spurt.

Dynamic Time Warping

Dynamic time warping was developed to align two signals with different dynamics.^[27–29] This method has been mainly applied to speech analysis and speech recognition. Suppose that two sequences $\{f(i), i = 1, \dots, M\}$ and $\{g(j), j = 1, \dots, N\}$ characterize two signals respectively. We want to find the best match between the two signals by some alignment w , based on minimizing a cost function. The classical cost function is given by

$$\inf_w \sum_{(i,j) \in w} (f(i) - g(j))^2.$$

Here $w = \{(i, j)\}$ is a warping path connecting $(1, 1)$ and (M, N) in a two dimensional square lattice and satisfying monotonicity and connectedness. This means that both coordinates of the parametrized path $w = \{(i(k), j(k)): k = 1, \dots, K; i(1) = j(1) = 1, i(K) = M, j(K) = N\}$ have to be nondecreasing, and that they can only increase by 0 or 1 when going from k to $k + 1$. Obviously, this is a minimization problem that can be solved efficiently by using dynamic programming. Fig. 2 is a demonstration of aligning one curve to another using dynamic time warping.

What controls the warping result is the cost function. In principle, a cost function could be any functional of the two input signals and a warping path, depending on the purpose of the application. For the purpose of aligning maxima, minima, and inflection points of curves, we incorporate derivatives of the signals into the cost function.^[30] Apart from heuristics, theoretical analysis and

Fig. 2 Dynamic time warping demonstration. Panels from top to bottom: two signals; warping function to align one curve to another; aligned signals

simulation analysis lend support to this idea. Incorporating higher order derivatives (the second derivative in particular) is possible in principle, but estimating higher order derivatives from noisy data is difficult. The cost function is given by

$$C(w) = \int F(f, f', g, g', w, \alpha)(x) \phi(w'(x)) dx$$

where f' is the derivative of f , α is a parameter to balance the alignment of curves and their derivatives, and the functional F is given by

$$F(f, f', g, g', w, \alpha)(x) = \alpha^2 \left(\frac{f(x)}{\|f\|} - \frac{g(w(x))}{\|g\|} \right)^2 + (1 - \alpha)^2 \left(\frac{f'(x)}{\|f'\|} - \frac{g'(w(x))}{\|g'\|} \right)^2.$$

Here $\|f\|$ is the infinite norm of f . The normalization is for reducing alignment error due to difference in amplitude. The penalty function ϕ is for reducing excessive alignment

and can be defined by a convex function with minimum $\phi(1) = 0$. This also makes the optimal alignment unique. To reduce the alignment error due to smoothing errors from estimating derivatives, the parameter α can be chosen from (0.5, 1).

Compared to the structural analysis as described in the section “Structural Analysis,” the advantage of dynamic time warping is that it automatically aligns structural points of two functions. It needs thus less a priori knowledge and less manpower, but structural analysis could still be preferable in difficult situations. Simulations had shown that dynamic time warping is an appropriate method for aligning two functions.^[30] The proposed cost function outperforms the classical cost function because of the use of derivatives, in particular when there are nonlinear shifts between functions. Furthermore, dynamic time warping with the proposed cost function produces smoother shift functions. As expected, the performance of warping depends mainly on the amount of true time shifts between two functions. The noise level does not affect the warping results very much since data are smoothed before warping.

Dynamic time warping produces a relative shift function between two curves. To align a set of sample curves to a common time scale, we need a reference curve. Then a warping function can be estimated by dynamic time warping and all curves can be aligned to this reference curve. Wang and Gasser^[31] have proposed the following iterative algorithm for aligning a set of curves.

Step (i): set the initial warping functions $\hat{w}_i^0(x) = x$ (noalignment).

Step (ii): compute the initial aligned average as

$$\hat{r}^0(x) = \frac{\sum_{i=1}^I \hat{r}_i(\hat{w}_i^0(x))}{I}.$$

Step (iii): update the warping functions by solving the minimization problems

$$C(\hat{w}_i^1) = \min_w C(w) = \int F(\hat{r}_i, \hat{r}_i', r^0, r^{0'}, w, \alpha)(x) \phi(w'(x)) dx.$$

Repeat steps (ii) and (iii) till convergence.

Under some assumptions, it can be shown that the algorithm converges and the aligned average is the shape function if the sample curves are generated from a SIM model.^[31] Because the algorithm estimates the differences in timing between the sample curves and the average curve, confidence regions can be calculated at feature points of the average curve.^[32]

Simulation results and some computational considerations discussed in Wang and Gasser^[31] are briefly described here. The parameter α can be chosen such that it produces the minimum cost $\min_w C(w)$. Choosing α from a few values {0.3, 0.5, 0.7} worked well in our simulations. On one hand, the penalty function ϕ should be strictly convex such that the solution of the minimization

problem of step (iii) is unique. On the other hand, ϕ should be flat so that it does not produce artificial warping functions by pushing toward the identity function. To avoid estimating derivatives of the warping functions, we have replaced the single penalty term $\phi(w'(x))$ with three conditions which are easy to handle in programming. Our simulations show that a few iterations (less than or equal to five iterations) produce nice results. In our simulations and applications, we use three iterations.

APPLICATION TO GROWTH DATA

The Zurich growth data is analyzed with the methods described in the sections “Linear Estimators” and “Analyzing Sample of Curves.” The data are the measurements of the growth (height, shoulder width, etc) of children from birth to adulthood. There are 120 boys and 112 girls. For each person, the measurements are taken quarterly from birth to one year old, semi-annually from one to two years old, annually from two to ten years old, and then semiannually from ten till pubertal growth has stopped. This results in at most 36 measurements per person. The actual number of measurements per person

ranges from 27 to 35, with an average of 32 measurements per person.

Here we discuss growth velocity of the shoulder widths of the children. Growth velocity is more informative because growth curves are simply increasing functions of age. From birth to two years old, the growth speed is high but it is simply decreasing. Therefore, we will analyze the growth speed of the children’s shoulder widths from 2 to 20 years old. The measurement unit is in centimeter.

Individual growth velocities (the derivatives of the growth curves) and second-order derivatives of the growth curves were estimated by kernel smoothing. The iterative algorithm described in the section “Dynamic Time Warping” was applied to estimate an average growth velocity of shoulder widths. Figs. 3 and 4 plot the results for boys and girls respectively.^[31]

From subgraph (b) of the Figs. 3 and 4, we see that the growth speed of a child’s shoulder widths changes quite a bit between individuals. The simple average of the growth speed of more than 100 children does catch the growth spurt at about age 14, but the amplitude of this peak is reduced. Furthermore, it misses the early spurt at about age 7 (see subgraph (d) of the Figs. 3 and 4). The mid growth spurt occurs at about the same age for boys and girls, but the major spurt

Fig. 3 Growth speed of shoulder width of boys. (a) shoulder width; (b) estimated individual growth speed; (c) estimated warping functions; (d) estimated average growth speed (solid line–aligned average; dashed line–average without alignment)

occurs at about age 13 for girls and at about age 15 for boys. These results agree with the findings of Gasser et al. ^[33,34]

APPLICATION TO BRAIN POTENTIALS

It is well known that event-related potentials obtained in repeated trials experience variable latencies of the components (for example, P3 and N1). The distortion is non-linear in the sense that the timing of features (say P1 N1 P2 N2 P3) in one trial cannot be linearly mapped to the timing of another trial. The conventional procedure for estimating the event-related potential is to average the repeated trials. The amplitude and latency variations among the single trials may lead to underestimating the amplitudes of the components (e.g., P3 and N1 of the average). The latency of a component of the average could be dictated by few trials with highest amplitudes.

To accurately estimate the event-related potential from these trials, the latency fluctuations have to be estimated first. Then the average of the aligned single trials is a good estimate of the event-related potential.^[35] An application to VP3 data is described below.

In a visual P3 (VP3) experiment, subjects are situated in front of a computer monitor and are presented with 280 visual stimuli with a uniform inter-stimulus interval of 1.6 seconds. There are 210 non-target stimuli in the shape of an outline of a square, 35 target stimuli in the shape of an X, and 35 novel stimuli, each a different colored polygon or other geometrical figure. The different types of stimuli are presented in random order. Subjects are instructed to respond to target stimuli by pressing a button. The VP3 data are recorded from 61 channels. After amplification by a factor of 10000, artifact threshold is set at 73.3 microvolts. Any trial with a value above the threshold is rejected. The number of the recorded single trials is different for different subjects and experimental conditions due to the artifact thresholding.

Fig. 5 plots the data from a subject and from one channel. There are 25 clean (no artifact) target trials recorded from the subject. The iterative algorithm of the section “Dynamic Time Warping” was applied to the target trials to obtain an estimate (warp-average) of the ERP from this channel. The result is plotted in Fig. 5. After the registration step, the structure of the brain potential comes out much more clearly.

KERNEL DENSITY ESTIMATION AND MULTIVARIATE REGRESSION

We will discuss briefly non-parametric regression in the setting of density estimation and high-dimensional regression.

Density Estimation

Based on independent observations x_i , $i = 1, \dots, n$, from an unknown distribution, we want to estimate the underlying density function f . The kernel estimator^[36] is given by

$$\hat{f}(x) = \frac{1}{nh} \sum_{i=1}^n K\left(\frac{x - x_i}{h}\right)$$

where h is a smoothing parameter and K is a non-negative kernel that integrates to 1. The properties of the density estimator are similar to those of the kernel estimator in regression case. For example, $\hat{f}$ is as smooth as K and the smoothing parameter can be chosen via cross-validation or plug-in method. Simulation by Hanson^[37] showed that kernel density estimation is valid and as good as a semi-parametric model for modeling censored lifetime data with a mixture of Gammas baseline survival density.

Multivariate Regression

Multivariate regression problem can be stated as

$$y_i = r(x_{i1}, \dots, x_{id}) + \sigma \varepsilon_i$$

for d predictors and some unknown surface r . The random errors ε_i are assumed to be independently distributed with mean $E(\varepsilon_i) = 0$ and variance $V(\varepsilon_i) = 1$. The regression methods discussed in section “Linear Estimators” can be easily extended to multivariate case (e.g., see Muller^[38] for kernel method in multivariate case). Fan et al.^[15] have shown that the optimal kernel is the spherical Epanechnikov kernel

$$K(x_1, \dots, x_d) = \frac{d(d+2)}{2S_d} (1 - x_1^2 - \dots - x_d^2)_+$$

where $S_d = 2\pi^{d/2} / \Gamma(d/2)$ denotes the area of the surface of the d -dimensional unit ball.

The difficulty in multivariate non-parametric regression is that data are sparse (“urge of dimensionality”). Several approaches have been proposed to reduce the dimensionality. The additive modeling^[39] approximates a d -dimensional surface by sum of one-dimensional functions. The one-dimensional functions can be estimated by the non-parametric methods of the section “Linear

Fig. 5 Top panel—25 VP3 trials from a channel; Bottom panel—average with (dash) and without (solid) alignment. Vertical unit is in microvolts and horizontal unit in milliseconds

Estimators.” The projection pursuit method^[40] projects the d -dimensional predictive space into a space with smaller dimension (linear transformations of the predictors) and then uses additive modeling. The linear transformations and the one-dimensional functions of the additive model are estimated with an iterative algorithm.

SOFTWARE

Software for non-parametric regression is widely available. Any statistical package likely includes programs for non-parametric regression. In addition to the “official” software, one can go to a package’s website (SAS, MATLAB, Splus, R, etc.) for many user contributed software offerings.

The standard software in pharmaceutical industry is SAS, which includes several non-parametric procedures for functional estimation. SAS/INSIGHT software provides non-parametric curve-fitting estimates from smoothing spline, kernel, loess, and fixed bandwidth local polynomial estimators that are alternatives to fitting polynomials. Some specific SAS procedures are PROC LIFETEST for estimating survival curves with censoring data, PROC KDE for density estimation, PROC LOESS for estimating regression surfaces, and PROC TPSPLINE for using thin-plate smoothing splines to approximate smooth multivariate functions.

For functional data analysis, Ramsay and Silverman have developed software in R, Splus, and MATLAB, which are available at <ftp://ego.psych.mcgill.ca/pub/ramsay/FDAfuns/>. For computing a structural average from a sample of curves, Fortran codes for the iterative algorithm of the section “Dynamic Time Warping” are available at the website <http://www.unizh.ch/biostat/Software/>. The kernel smoothing software that we used is also available from this website.

CONCLUSION

Non-parametric methods allow more flexibility for the functional dependence of a response variable on predictors than a typical parametric model does, and these methods are well suited for situations where little is known about the process under study. The linear methods discussed in the section “Linear Estimators” perform well and have similar asymptotic properties. A comparison of kernel smoothing and wavelet shrinkage by Wang et al.^[41] has shown that both methods work well.

The crucial step in applying the non-parametric regression methods is to choose the smoothing parameter. Local bandwidth selection based on data (plug-in, cross-validation) is able to preserve fine structures of the regression function. Another major step is boundary correction for kernel estimators. Simulations by Hess et al.^[1] have confirmed the advantage of local bandwidth selection and boundary correction in estimating hazard functions.

We have applied the iterative algorithm based on dynamic time warping to two applications in order to construct a timing-aligned average curve from a sample of curves. The iterative algorithm either brings out new feature of the growth curves or enhances features of the brain potentials.

Odds Ratio

Dongsheng Tu

NCIC Clinical Trials Group, Queen's University, Kingston, Ontario, Canada

Abstract

The objective of this entry is to introduce the definition of the odds ratio and its statistical inferences based on data from randomized clinical trials. Some other topics related to odds ratio will also be discussed.

Keywords: Inference; Odds ratio; Regression.

INTRODUCTION

In epidemiological literature, odds ratio has been frequently used to assess the strength of the association between a binary exposure variable and a binary disease outcome. It was first introduced by Cornfield^[1] as a measure of relative risk in retrospective studies, where the other more intuitive measure, the rate ratio, cannot be estimated. When the baseline risk of the disease is low, the odds ratio provides a good approximation to the risk ratio. The odds ratio has also some mathematical advantages: It takes values between 0 and infinity, which is not the case for rate ratio; if the outcome in the analysis is reversed from positive to negative, we get a reciprocal odds ratio. Its other statistical advantages include that it derives naturally from the logistical regression models and that it arises as a natural parameter in a conditional distribution that is the base for the exact inference.^[2,3]

For a clinical trial with a binary outcome as the primary endpoint, such as whether the symptom of a patient has disappeared after a certain period of treatment, the difference between two treatment arms is usually measured by the difference in the rates for the outcome of interest. The ratio of these two rates is also often calculated, which provides a measure for the relative effect of the treatments. Recently, odds ratio has also appeared in clinical trial literature as an alternative measure of relative treatment effects (e.g., see Ref. [4]). This is especially true when a meta-analysis of several clinical trials is involved. The objective of this entry is to introduce the definition of the odds ratio and its statistical inferences based on data from randomized clinical trials. Some other topics related to odds ratio will also be discussed.

DEFINITION

Let P_T be the probability of having an outcome of interest, which can be either positive (e.g., the patient responded to a treatment) or negative (e.g., the disease of the patient progressed), for a patient treated by a test treatment (a new drug or procedure) and let P_C be the probability for

a patient treated by a control, which may be a standard treatment or a placebo. The odds that a patient will have an outcome of interest instead of not have an outcome of interest when one has received a test treatment is $O_T = P_T/(1 - P_T)$. The corresponding odds can be similarly defined for the patients treated by a control. Then the ratio of these two odds is defined as the odds ratio for the test group vs. control group, which can be written as: $\psi = [P_T(1 - P_C)]/[P_C(1 - P_T)]$. The odds ratio is always positive and has a range from 0 to infinity. $\psi = 1$ implies that there is no difference between two treatment groups in terms of the outcome of interest (i.e., $P_T = P_C$). When $\psi > 1$, patients in the test group will be more likely to have the outcome of interest than those in the control group. The converse is true when $0 < \psi < 1$. When the outcome of interest is adverse (e.g., disease progress or death), $1 - \psi$ is often defined as relative odds reduction.

Suppose, in a randomized clinical trial, that n_T patients were assigned to receive the test treatment and that n_C patients were assigned as the control. Let X_T and X_C be the observed numbers of patients in the test group and control group, respectively, who had outcome of interest. Because X_T and X_C are independent, the likelihood of these observations is a product binomial:

$$L(P_T, P_C | X_T = x_T, X_C = x_C) = \binom{n_T}{x_T} P_T^{x_T} (1 - P_T)^{n_T - x_T} \binom{n_C}{x_C} P_C^{x_C} (1 - P_C)^{n_C - x_C}$$

The natural estimates, which are also maximum likelihood estimates, for P_T and P_C , respectively, are:

$$\hat{P}_T = \frac{X_T}{n_T} \quad \text{and} \quad \hat{P}_C = \frac{X_C}{n_C}$$

Therefore a point estimate for ψ , which is also a maximum likelihood estimate and called also just as odds ratio, can be defined as:

$$\hat{\psi} = \frac{\hat{P}_T(1 - \hat{P}_C)}{(1 - \hat{P}_T)\hat{P}_C}$$

ASYMPTOTIC INFERENCES

Haldane^[5] derived the asymptotic variance of $\hat{\psi}$, which would be used to construct an asymptotic $100(1 - \alpha)\%$ confidence interval for ψ . But because the estimate of the odds ratio is always positive, its distribution is skewed and therefore a normal approximation might be very inaccurate. In this case, it is a common statistical practice to make first a transformation, such as logarithm transformation, to the estimate and then to derive a confidence interval based on transformed estimators. Form the results of Haldane,^[5] the asymptotic variance for $\ln(\hat{\psi})$ can be derived as:

$$v[\ln(\hat{\psi})] = \frac{1}{n_T P_T (1 - P_T)} + \frac{1}{n_C P_C (1 - P_C)}$$

It can be estimated by:

$$\hat{v}[\ln(\hat{\psi})] = \frac{1}{n_T \hat{P}_T (1 - \hat{P}_T)} + \frac{1}{n_C \hat{P}_C (1 - \hat{P}_C)}$$

Therefore an asymptotic $100(1 - \alpha)\%$ confidence interval based on a logarithm transformation for ψ is: $\exp(\ln(\hat{\psi}) \pm z_{1-\alpha/2} \sqrt{\hat{v}[\ln(\hat{\psi})]})$ where $z_{1-\alpha/2}$ is the $1 - \alpha/2$ percentile of a standard normal distribution. This confidence interval is sometimes called the logit confidence interval after it was first derived by Woolf.^[6] It is widely recommended as a satisfactory approximation except when any one of X_T and X_C is too small or too close to n_T and n_C , respectively. In the later case, exact methods that will be introduced in “Exact Inferences” would be used. In the extreme cases when one of X_T , X_C , $n_T - X_T$, $n_C - X_C$ is 0, Haldane^[5] and Anscombe^[7] suggested to add 0.5 to each of these numbers and to use the following estimator, which is sometimes called the Haldane-Anscombe 1/2 correction estimator of ψ :

$$\hat{\psi}_1 = \frac{\left(\hat{P}_T + \frac{0.5}{n_T} \right) \left(1 - \hat{P}_C + \frac{0.5}{n_C} \right)}{\left(1 - \hat{P}_T + \frac{0.5}{n_T} \right) \left(\hat{P}_C + \frac{0.5}{n_C} \right)}$$

The associated $100(1 - \alpha)\%$ confidence interval for ψ is: $\exp(\ln(\hat{\psi}_1) \pm z_{1-\alpha/2} \sqrt{\hat{v}[\ln(\hat{\psi}_1)]})$ where

$$\begin{aligned} \hat{v}[\ln(\hat{\psi}_1)] = & \frac{1 + \frac{1}{n_T}}{n_T \left(\hat{P}_T + \frac{0.5}{n_T} \right) \left(1 - \hat{P}_T + \frac{0.5}{n_T} \right)} \\ & + \frac{1 + \frac{1}{n_C}}{n_C \left(\hat{P}_C + \frac{0.5}{n_C} \right) \left(1 - \hat{P}_C + \frac{0.5}{n_C} \right)} \end{aligned}$$

Gart and Zweifel^[8] showed that $\hat{\psi}_1$ and its variance estimator have smaller asymptotic bias and mean square error in comparison to $\hat{\psi}$ and its variance estimator even when none of X_T , X_C , $n_T - X_T$, $n_C - X_C$ is 0. Some authors,

such as Mantel,^[9] prefer not to add the 0.5 correction factor. Instead, if $\hat{\psi}$ is infinite for a particular dataset, they suggested that a lower confidence limit for ψ be calculated using an exact method, which will be introduced in “Exact Inferences.”

The above methods can also be used to test hypotheses about ψ . Because $H_0: \psi = 1$ is equivalent to $H_0: P_T = P_C$ and $H_a: \psi > (<)1$ is equivalent to $H_a: P_T > (<)P_C$, conventional statistical tests, such as Pearson's chi-square test or Mantel-Haenszel test, for the association in a 2×2 table can also be applied to test hypotheses about P . The details can be found in standard textbooks such as that of Lachin.^[3]

It should be noted that these conventional tests might yield different results from that derived from the confidence intervals introduced before. For example, a 95% confidence interval for ψ may cover 1 when the p value of the Person's chi-square test is less than 0.05. If it is desired to include both results from the hypothesis testing and confidence interval, a test-based confidence interval may be preferred. Let T be a test statistic for the hypotheses $H_0: \psi = 1$ vs. $H_a: \psi \neq 1$. Then an asymptotic $100(1 - \alpha)\%$ test-based confidence interval for ψ is:

$$\exp\left(\ln(\hat{\psi}) \pm \frac{z_{1-\alpha/2} \ln(\hat{\psi})}{\sqrt{T}}\right)$$

A short summary of the results involving comparisons between the logit and the test-based confidence interval can be found in Section 3.1.4 of Sahai and Khurshid.^[10]

EXACT INFERENCES

The exact confidence interval for ψ is based on the conditional distribution of X_T and X_C given $m = X_T + X_C$, which can be written as:

$$\begin{aligned} P(X_T = x_T | m = x_T + x_C, \psi) \\ = \frac{\binom{n_T}{x_T} \binom{n_C}{m - x_T} \psi^{x_T}}{\sum_{i=\alpha_1}^{\alpha_u} \binom{n_T}{i} \binom{n_C}{m - i} \psi^i} \end{aligned}$$

where $\alpha_1 = \max(0, m - n_C)$ and $\alpha_u = \min(m, n_T)$. This conditional distribution depends only on ψ . Therefore an exact $100(1 - \alpha)\%$ confidence interval $(\hat{\psi}_l, \hat{\psi}_u)$ for ψ can be obtained by solving the equations:

$$\frac{\alpha}{2} = \sum_{x=x_T}^{\alpha_u} P(x | m, \hat{\psi}_l) \quad \text{and} \quad \frac{\alpha}{2} = \sum_{x=\alpha_1}^{x_T} P(x | m, \hat{\psi}_u)$$

It may be noted that when we use this confidence interval to describe the range of the difference between two treatment groups, for consistency, ψ should also be estimated based on the conditional distribution, that is, by maximizing the conditional likelihood defined by

$L(\psi|x_T, m) = p(x_T|m, \psi)$. This conditional maximum likelihood estimator may be different from $\hat{\psi}$, which is the maximum likelihood estimator based on product binomial distribution.

We can also construct an exact test based on this conditional distribution. This is usually called the Fisher's exact test. For one-sided hypotheses $H_0: \psi = 1$ vs. $H_a: \psi > 1$ or $H_a: \psi < 1$, the p values, respectively, of Fisher's exact test is defined as:

$$P_u = \sum_{x=x_T}^{a_U} P(x|m, \psi=1) \quad \text{or} \\ p_l = \sum_{x=a_L}^{x_T} P(x|m, \psi=1)$$

The p value of the Fisher's exact test for two-sided hypotheses $H_0: \psi = 1$ vs. $H_a: \psi \neq 1$ is defined as:

$$p = \sum_{x=a_L}^{a_U} \left\{ I \left[P(x|m, \psi=1) \leq P(x_T|m, \psi=1) \right] \times P(x|m, \psi=1) \right\}$$

where $I(\cdot)$ is the indicator function.

For randomized clinical trials, some authors argued that it might be artificial to assume that m is fixed and to use the test based on the conditional distribution. Others argued that conditioning on a sufficient statistic to eliminate nuisance parameters is an appropriate statistical practice no matter if m can be assumed fixed. Besides these philosophic differences, Agresti^[11] pointed out that the root of most objections to conditional approach is their conservatism as a result of discreteness of the distribution. Some unconditional exact tests were proposed. The p values of these tests are defined as:

$$p = \sup_{0 \leq \rho \leq 1} P(T \geq t | P_T = P_C = \rho)$$

where T is a given test statistic and t is the observed value of T . For example, Suissa and Shuster^[12] derived an unconditional exact test by taking T as the unpooled z test statistic. There are still debates on which method is more suitable. Some compromises have been proposed such as to adjust exact methods based on mid p values (see a review by Berry and Armitage^[13]). More discussions about this topic can be found in Agresti.^[11]

NUMERICAL EXAMPLE

A randomized clinical trial has been conducted by the AIDS Clinical Trials Group to study the safety and efficacy of thalidomide for the treatment of esophageal aphthous ulcers in patients infected with HIV.^[4] Eleven patients were randomized to receive thalidomide (test treatment) and 13 were randomized to receive placebo (control).

The primary outcome of interest was a complete healing of aphthous ulcers at the 4-week endoscopic evaluation. Eight patients in the thalidomide group and three patients in the placebo group had outcome of interest. The odds ratio of test vs. control group is 8.89. The associated 95% legit confidence interval is (1.40, 57.57). The Haldane-Anscombe 1/2 correction estimate of the odds ratio is 7.28 with a 95% confidence interval from 1.28 to 41.34. The chi-square test statistic for $H_0: \psi = 1$ vs. $H_a: \psi \neq 1$ is 5.92 with a p value of 0.015. A 95% confidence interval based on the chi-square test is (1.53, 51.66), which is farther away from 1 than the legit interval.

Because the numbers of patients in both groups in this example are small, an exact inference may be preferred. The odds ratio estimate based on the conditional distribution is 7.95. An exact 95% confidence interval based on the conditional distribution is (1.06, 84.35). The p value of the two-sided Fisher's exact test is 0.038, which is more than double that of chi-square test.

RELATIONSHIP WITH OTHER MEASURES

The relationship of odds ratio with other measures, such as the difference or the ratio of the probabilities of having an outcome of interest between two groups, is nonlinear. Let $D = P_T - P_C$ be the difference of these probabilities. It is easy to see when P_C is known:

$$\psi = \frac{(P_C + D)(1 - P_C)}{P_C(1 - P_C - D)} = 1 + \frac{1}{\frac{P_C(1 - P_C)}{D} - P_C}$$

It is an increased function of D . For the ratio of the probabilities, denoted by R , we have:

$$\psi = \frac{(P_C R)(1 - P_C)}{P_C(1 - P_C R)} = R \left(\frac{1 - P_C}{1 - P_C R} \right) \text{ or } R = \frac{\psi}{1 + P_C(\psi - 1)}$$

ψ is close to R whenever P_C and P_T are small (i.e., the probability to have an outcome of interest is rare in both treatment groups). But when $\psi > 1$, we have always $\psi > R$. The difference between ψ and R can be very large when P_C is very large. When $\psi < 1$, we have $\psi < R$. In this case, ψ is farther away from 1 than R when P_C becomes very large.

In the example introduced in "Numerical Example," the estimates of D and R are 0.50 and 3.15, respectively. Because both the estimates of P_C and P_T are large (0.23 and 0.73, respectively), there is a big difference between the estimates of ψ and R .

For a single study, all three measures would be a choice for the measurement of the difference between groups when it exists. Sackett and Cook^[14] recommended that one absolute measure of efficacy (such as rate difference or its reciprocal, which is called the number of patients needed to be treated) and some relative measure of efficacy be included in the description of efficacy

results from a randomized clinical trial. Both rate ratio and odds ratio would be used as a measure of relative efficacy. Sinclair and Bracken^[15] argued that rate ratio might be more appealing to clinicians. As pointed out before, the odds ratio has some mathematical and statistical advantages, which may be the reasons they continue to be quoted in clinical literature.^[2] For a single study with moderate or large sample size, all three measures will likely reach similar conclusions. However, when there are multiple 2×2 tables such as from multiple strata when we perform a stratified analysis in a single study or a meta-analysis of many different studies, the conclusions reached may depend on the measure chosen to summarize the results.^[3]

OTHER RELATED TOPICS

Sample Size Calculations

Wang et al.^[16] presented sample size calculation formulas for clinical trials with odds ratio as primary endpoint under various designs and types of hypotheses. Specifically, assume that one is interested in testing hypotheses given by $H_0: \psi = 1$ vs. $H_a: \psi \neq 1$ in a two group parallel design with 1 to 1 randomization. Then the sample size required in each group to detect, with power $1 - \beta$ and two-sided significance level α , a difference between two groups as measured by an odds ratio ψ is:

$$n = \frac{(z_{1-\alpha/2} + z_{1-\beta})^2}{\ln^2(\psi)} \left[\frac{1}{P_T(1-P_T)} + \frac{1}{P_C(1-P_C)} \right].$$

Adjusted Odds Ratio in Logistic Regression Models

Although there are still some controversies, the treatment effect in clinical trials is often adjusted for some prognostic factors or other baseline variables that are not balanced by randomization. When the endpoint of a trial is binary, a logistic regression model is often used to perform this adjustment. Assume that Y ($= 1$ or 0) is the binary outcome and $Y = 1$ implies the outcome of interest. Let $P = P(Y = 1)$ be the probability of having an outcome of interest for a patient in the study (no matter which group one was assigned to) and Z is an indicator variable that takes a value of 1 if this patient is assigned to be treated by the new treatment and 0 otherwise. Assume that $X_1, X_2, \dots, X_K$ are the K prognostic factors or covariates for which we would like to adjust for. A logistic regression model is defined as:

$$\ln\left(\frac{P}{1-P}\right) = \alpha_0 + \beta Z + \delta_1 X_1 + \dots + \delta_K X_K$$

where $\alpha_0, \beta, \delta_1, \dots, \delta_K$ are unknown parameters. It is easy to show that:

$$\exp(\beta) = \frac{\frac{P(Y=1|Z=1, X_1, \dots, X_K)}{P(Y=0|Z=1, X_1, \dots, X_K)}}{\frac{P(Y=1|Z=0, X_1, \dots, X_K)}{P(Y=0|Z=0, X_1, \dots, X_K)}}$$

which is the ratio of the odds of having an outcome of interest instead of not having an outcome of interest when treated by a test procedure to that when treated by a control after controlling for the effects of all other covariates. $\exp(\beta)$ is usually called the adjusted odds ratio. It can be estimated by using maximum likelihood methods or some exact methods based on conditional distributions. The details can be found in Chapter 4 of Agresti.^[17]

Use of the Odds Ratio in Therapeutic Equivalence Clinical Trials

In a therapeutic equivalence trial with a binary end point, we are interested in testing whether two treatments have the same efficacy or the test treatment is not inferior to a control. We consider here only the former case. Tu^[18,19] compared some statistical procedures when the difference of outcome rates is used as a measurement of efficacy difference between two treatments. In this case, there is some difficulty in determining the acceptance limits (e.g., see Weng and Liu^[20] and Bristol^[21] for a detailed discussion). Because of this, Weng and Liu^[20] suggested that some other statistical procedures, such as those based on the odds ratio, might be more appropriate. Tu^[22] discussed some issues related to the use of the odds ratio in establishing therapeutic equivalence with binary end points. In this case, the interval hypotheses for the therapeutic equivalence of test and control can be formulated as follows: $H_0: \psi \leq \xi_L$ or $\psi \geq \xi_U$ vs. $H_1: \xi_L < \psi < \xi_U$ where ξ_L and ξ_U are prespecified lower and upper acceptance limits, respectively. A one-sided logit procedure for the testing of these interval hypotheses is to reject H_0 at the α level if $T_{LG} > z_\alpha$ and $T_{UG} < -z_\alpha$, where:

$$T_{LG} = \frac{\ln(\hat{\psi}_1) - \ln(\xi_L)}{\sqrt{\hat{v}[\ln(\hat{\psi}_1)]}} \quad \text{and} \quad T_{UG} = \frac{\ln(\hat{\psi}_1) - \ln(\xi_U)}{\sqrt{\hat{v}[\ln(\hat{\psi}_1)]}}$$

Tu^[22] evaluated some statistical properties of this and some more complicated procedures. It was found out that if we set up the acceptance interval as (0.8, 1.25), which was used for the assessment of bioequivalence based on the ratio of the means of two normal distributions, the power of the logit procedures will be very small even

when $\psi = 1$. This means that a huge sample size (on the order of thousands) would be required if we want the test to have an 80% power. By comparing the acceptance interval with that suggested for the rate difference, it was found that the interval (0.43, 2.33) might be a reasonable alternative choice. According to the guidelines for the interpretation of the values of odds ratio in Greenberg,^[23] when the true odds ratio is covered by this interval, the difference between two groups is moderate at best while true odds ratio falling into (0.8, 1.25) implies no difference. When this acceptance interval is used, the procedures based on the odds ratio have the following advantage over the procedures based on the difference: They automatically make the acceptance interval narrow when the cure rates of the drugs are large. For example, when $P_R = 0.5$, $0.43 \leq \psi \leq 2.33$ implies $-0.2 \leq P_T - P_R \leq 0.2$; and when $P_R = 0.9$, $0.43 \leq \psi \leq 2.33$ implies $-0.1 \leq P_T - P_R \leq 0.05$.

Combining Odds Ratios in Stratified or Meta-Analyses

A study with a binary endpoint may be stratified based on some baseline patient characteristics and a stratified analysis by combining treatment comparisons in the different strata may be desired. Or there were several studies that used the same binary endpoint to evaluate the same treatments and we would like to perform a meta-analysis to combine evidences about the treatment effect from these different studies. Assume that treatment differences in all strata or studies are assessed by odds ratios that are the same across all the strata or studies. An asymptotic method by Mantel and Haenszel^[24] would be used to test whether this common odds ratio is one or, together with a variance estimator proposed by Robins et al.,^[25] to construct an asymptotic confidence interval for the common odds ratio. An exact confidence interval can be calculated based on a method proposed by Mehta et al.^[26] In meta-analyses, the homogeneity of the odds ratios would be tested by an exact test proposed by Zelen^[27] or an asymptotic test proposed by Breslow and Day.^[28] Some other methods for the assessment of odds ratio homogeneity or the inference on the common odds ratio can be found in Chapter 4 of Lachin.^[3] When there is some heterogeneity in odds ratio, a random effect model method by DerSimonian and Laird^[29] would be used to obtain an overall assessment of the treatment effect.

Local and Cumulative Odds Ratio in $2 \times K$ Tables

In some clinical trials, the endpoint may have more than two categories. For example, in an FDA draft guideline for the performance of a bioequivalence study for tretinoin products, it was recommended that the overall improvement in the patient's acne be evaluated globally on the following scale: 1 = *cleared or marked improvement*: between 76% and 100% clearance of acne lesions;

2 = *moderate improvement*: between 50% and 75% clearance of acne lesions; 3 = *slight improvement*: less than 50% clearance of acne lesions; and 4 = *no change or worse*.^[30] In general, assume that the endpoint of a trial has K ordered categories and let π_{Tj} be the probability that a patient treated by the test treatment has a response in category j and let π_{Cj} be the corresponding probability for a patient treated by the control. The relative difference between the test treatment and the control can be described by $k - 1$ local odds ratio $\phi_j = (\pi_{Rj}\pi_{T(j+1)})/(B_{Tj}\pi_{R(j+1)})$, $j = 1, 2, \dots, k - 1$. Whether these two treatments are different would be assessed by testing the null hypothesis $H_0: \phi_1 = \dots = \phi_{k-1} = 1$. When the categories are not ordered, Pearson's chi-square test or Fisher's exact test can be used to test H_0 . If there is a natural ordering, the asymptotic or exact distribution of a Wilcoxon midrank test statistic can be used to perform an asymptotic or an exact test, respectively, for the above hypothesis.^[31,32] Another way to measure the difference between two treatments when endpoint is ordinal categorically is to use the so-called cumulative odds ratios $\zeta_j = [Q_{Tj}(1 - Q_{Cj})]/[(1 - Q_{Tj})Q_{Cj}]$, where $Q_{Tj} = \pi_{T1} + \dots + \pi_{Tj}$, $j = 2, \dots, k$, and Q_{Cj} is defined similarly. Assume that all ζ_j are the same (so-called proportional odds model). Jones and Whitehead^[33] derived a score test for the null hypothesis that the common cumulative odds ratio is 1. Both measures were used by Tu^[34] to test an interval hypothesis in therapeutic equivalence trials with ordinal categorical endpoints.

CONCLUSION

Although there has been continuous debate on its interpretations in clinical trials,^[35] the odds ratio is a useful measure of relative treatment effects in clinical trials with binary or categorical end points because of its many attractive mathematical and statistical properties. It should not, however, be confused with the rate ratio—the other measure of relative treatment effect. They may be quite different when the rate of the control group is not too small, as is the case in many clinical trials.

Oncology Clinical Trials: Efficient Dose-Finding Designs

Erik Rasmussen, Qi Jiang, and Chunlei Ke

Amgen, Thousand Oaks, California, U.S.A.

Abstract

Dose finding for oncology therapeutics remains a challenge in drug development. The past decades have seen many methodologic advances for dose finding in oncology drug development, but implementation of these new methods has been less than ideal, as the historic 3+3 design remains the most commonly implemented design. This chapter provides an overview of dose-finding methodologies in oncology trials. We focus on the commonly implemented designs and designs that if implemented more frequently would likely improve oncology dose finding. Designs summarized in detail include the 3+3 design, Bayesian logistic regression model, and modified toxicity probability interval design; each of these designs identifies the maximum tolerated dose. Descriptions are also provided for the Phase I/II design to use both toxicity and efficacy to identify a dose with maximum benefit–risk and the partial order continual reassessment method design to identify a maximum tolerated combination of two or more oncology therapeutics. Additionally, we provide practical recommendations on when to implement these methodologies to possibly improve oncology dose finding. Finally, recent contributions to dose-finding methodologies in oncology clinical trials are summarized.

Keywords: Bayesian logistic regression; BLRM; Continual reassessment method; CRM; Dose finding; Maximum tolerated dose; MTD; Phase I.

INTRODUCTION

Researchers and developers of oncology therapeutics have had many successes over the years. Five-year survival rates have improved meaningfully for many tumor types. Compared to the estimated 5-year survival rate in 1975–1977, the 5-year survival rate from 2003 to 2009 increased as follows^[1]:

- *Multiple myeloma*: It improved 5-year survival rate from 25% to 45%.
- *Non-Hodgkin's lymphoma*: It improved 5-year survival rate from 47% to 71%.
- *Prostate*: It improved 5-year survival rate from 68% to 100%.

Despite these successes, oncology drug development has seen many drug development failures. The Biotechnology Innovation Organization estimates that between 2006 and 2015 only 40% of oncology Phase III studies were positive.^[2] Suboptimal dosing is one possible cause of Phase III failures. Dose finding involves testing different dose levels of a drug in order to characterize the benefit–risk profile with the goal of identifying a dose with an optimal benefit–risk profile. The ideal benefit–risk profile would be

a 100% cure rate with no safety issues. In reality, the ideal scenario never occurs and dose finding is done to balance the trade-off between efficacy and toxicity. Many effective dose-finding methods have been developed that, if implemented more frequently, would likely improve the success rate in oncology drug development.

The primary purpose of this article is to provide an overview of dose-finding methodologies in oncology trials and to provide recommendations for clinicians and statisticians working in dose-finding oncology trials. The overview of dose-finding methodologies is summarized by dose-finding objective and class of design. For illustration purposes, the most frequently used design in a class, if applicable, is described in detail with other designs in the class referenced. Additionally, recent contributions to dose-finding methodologies in oncology clinical trials are introduced and referenced. The remainder of this article is structured as follows: designs to identify monotherapy maximum tolerated dose are reviewed in Section “Designs to Identify Monotherapy Maximum Tolerated Dose,” designs to identify the recommend Phase II dose in Section “Designs to Identify the Recommended Phase II Dose,” and designs to identify the combination maximum tolerated dose in Section “Designs to Identify the Combination MTD.” Recommendations regarding the use of these

designs will also be provided for each section. Finally, recent trends in dose finding are discussed in Section “Recent Trends in Dose Finding.”

DESIGNS TO IDENTIFY MONOTHERAPY MAXIMUM TOLERATED DOSE

An investigational new drug needs to obtain safety data and demonstrate safety as a monotherapy treatment in a first-in-human (FIH) study before subjects in additional clinical trials can be enrolled. The primary objective of the FIH study is usually to estimate the MTD. Various clinical trial endpoints are used to identify the MTD. The most commonly used endpoint is dose-limiting toxicity (DLT); DLT encompasses a range of adverse events that are determined to be severe enough to warrant discontinuation of dosing. Though infrequently used, ordinal toxicity and time to toxicity event are clinical endpoints that incorporate additional clinically relevant information into the dose-finding process. Occasionally, both the dose level and the dosing schedule are varied in order to identify the MTD. Sections “Designs Based on DLT” through “Designs That Optimize Dose Level and Schedule” summarize such designs to identify the MTD. Section “Discussion and Recommendations” provides recommendations regarding the use of these designs to improve dose finding.

Designs Based on DLT

Multiple methods and approaches have been proposed and evaluated for dose finding using DLT as the primary endpoint. We classify these methods into three categories. First, rule-based designs use dose escalation/de-escalation rules to treat subjects at various dose levels with the goal of converging to treat subjects at the MTD. Second, model-based designs estimate the MTD by estimating the dose–toxicity relationship. Finally, interval designs combine the aspects of rule-based and model-based designs and dose-find using toxicity probability intervals (TPIs).

Rule-Based Designs

Rules-based designs use dose escalation/de-escalation rules to treat subjects at various dose levels with the goal of converging to treat subjects at the MTD. The most commonly used rule-based approach is the 3+3 design.^[3] The 3+3 design is described next in detail; additional rule-based designs are referenced.

3+3 Design The 3+3 design uses enrollment and dosing rules to identify the MTD. The MTD is defined as the highest dose level with at least six subjects treated and fewer than 33% of subjects experiencing a DLT. In designing the 3+3 study, researchers specify the dose levels of interest. The tolerability of the lowest planned dose is

evaluated followed by a sequential evaluation of escalated dose levels until MTD identification. The following rules guide subject enrollment and dosing:

- A cohort of three subjects is enrolled and treated at a dose level. Limiting enrollment to an initial three subjects reduces the number of subjects exposed to overly toxic dose levels and reduces the number of subjects treated at sub-therapeutic dose levels.
If no DLTs, the next cohort of three subjects is enrolled and treated at an escalated dose level.
If one DLT occurs, the current cohort is expanded and three additional subjects are enrolled.
If two or more subjects experience a DLT, the dose is de-escalated for the next cohort.
- A dose level is considered to be not tolerated whenever two or more subjects experience a DLT, regardless of the cohort size ($n = 3$ or 6).
- At least six subjects must be treated at a dose level for the dose level to be considered the MTD.

The sample size for a 3+3 design is adaptive and depends on the dose level where toxicity is observed in accordance with planned dose levels. Designs that aggressively start at a high dose level will likely observe early toxicity, and therefore identify the MTD with a minimal number of subjects (e.g., 9–12 subjects). Designs that start at a low dose with many planned dose levels due to cautious dose escalation will have larger sample sizes (e.g., 30 subjects).

Other Rule-Based Designs A common modification of the 3+3 design is called an accelerated titration design in which single subject cohorts are enrolled until the initial DLT is observed. Simon et al.^[4] describe multiple variations of accelerated titration designs and evaluate the operating characteristics of these designs. Up and down designs are another class of rule-based designs; Storer^[3] describes a number of these up and down designs. Ivanova et al.^[5] evaluate the properties of several up and down designs, and they recommend alterations to improve the operating characteristics of these designs.

Model-Based Designs

Model-based designs determine the MTD by estimating the dose–toxicity relationship. A one- or two-parameter model is typically used. A model-based approach to oncology dose finding was initially proposed by O’Quigley et al. in 1990^[6] using a method called the continual reassessment method (CRM). CRM is designed to treat each subject near the optimal dose level, where the optimal level is estimated from a dose–toxicity model. As data accrue, the model is updated and optimal dose levels are reassessed.

Due to practical concerns, the originally proposed CRM is not implemented in practice. The CRM concept greatly influenced additional research on model-based dose-finding

designs with many of these designs being implemented in practice. A commonly used model-based approach is the Bayesian logistic regression model (BLRM). This design is described next in detail; additional model-based designs are referenced.

Bayesian Logistic Regression Model As described by Neuenschwander et al.,^[7] BLRM makes model-based dose-level recommendations with the model being reassessed throughout the study. Additionally, BLRM implements the concept of escalation with overdose control.^[8]

Model BLRM models the probability of toxicity (p_i) using the logistic transformation:

$$\begin{aligned}\log\left[p_i/(1-p_i)\right] &= \text{logit}(p_i) \\ &= \log(a) + \exp[\log(b)] \log(d_i/d_{\max})\end{aligned}$$

The value d_i represents the dose level of interest and $d_{\max}$ represents the maximum planned dose. The values a and b are model parameters. Since the Bayesian framework is used, the parameters a and b are random variables with the pair $\log(a)$ and $\log(b)$ assumed to follow a bivariate normal distribution. The prior for $\log(a)$ and $\log(b)$ is calibrated using at least two quantiles for each dose level (e.g., 95% credible interval) where these quantiles are specified by the study team. These team-specified quantiles are compared to model-derived quantiles in order to select the prior. The bivariate normal distribution that minimizes the discrepancy between model-derived quantiles and team-specified quantiles is selected as the prior for $\log(a)$ and $\log(b)$.

Overdose Control BLRM makes dose recommendation based on the intervals from the Bayesian posterior distribution. The probability of DLT is described in four intervals:

- Underdosing: (0, 0.20]
- Targeted toxicity: (0.20, 0.35]
- Excessive toxicity: (0.35, 0.60]
- Unacceptable toxicity: (0.60, 1.00]

The recommended dose is the dose level that maximizes the targeted toxicity, while controlling at acceptable levels the risk of excessive or unacceptable toxicity (e.g., <25% probability).

Practical Notes Practical implementation of the BLRM requires a list of planned dose levels with dosing beginning at the lowest planned dose level. Dose-level decisions will be made after a cohort of safety data are observed; a common cohort size is $n = 2$ subjects. Though the BLRM uses a model-based method to control for overdose, practical safety constraints can be added (e.g., never dose-escalate more than twofold above the current dose level). The maximum

sample size (e.g., $n = 30$ subjects) and other design features such as the early stopping rule are chosen a priori for the BLRM design. Simulations should be done to evaluate the impact of these design features on operating characteristics such as accuracy in identifying the MTD, number of DLTs, and trial duration. BLRM may perform poorly when toxicity is observed early in the study. BLRM uses a two-parameter model which can lead to erratic dose recommendations at small sample sizes (see the work of Shu and O'Quigley^[9]). When it is anticipated that toxicity will be observed early in the study at small sample sizes, a design using a one-parameter model likely would have better operating characteristics than BLRM (see Section "Other Model-Based Designs" for a description of one-parameter designs). Despite this concern, BLRM performs well in common drug development scenarios where toxicity is not observed until later in the study, and the two-parameter model has sufficient data to make reasonable dose-level recommendations.

Other Model-Based Designs Additional model-based designs build on the original CRM design with accommodations for practical concerns. Addressing the overdose risk from making dose-level decisions using data from a single subject, Goodman et al.^[10] propose a group CRM in which cohorts of $n = 3$ subjects are treated and evaluated prior to making a dose-level decision. Addressing the overdose risk using a model-based projection of toxicity risk, Moller^[11] proposes capping the level of dose escalation regardless of the model-based recommendation. Additional practical modifications to the original CRM design have been proposed (see the works of Goodman et al.^[10] and Faries and Whitehead et al.^[12,13]).

Researchers have investigated the specification of a Bayesian prior in model-based dose finding. Generally, either one- or two-parameter models have been used for the prior. The one-parameter model requires prespecified skeleton probabilities in a working model where under the Bayesian framework the skeletons can be interpreted as the prior understanding of the toxicity probability for each dose level under investigation. O'Quigley and Zohar, Lee and Cheung, and Daimon et al.^[14–16] generally show that the one-parameter model is robust and efficient in estimating MTD, if an appropriate skeleton is chosen. Iasonos and O'Quigley^[17] discuss the aspects of choosing the skeleton in the setting of a two-stage design. Whitehead and Williamson^[18] describe two-parameter models. Neuenschwander et al.^[7] describe a two-parameter model that they generally prefer to the one-parameter model as it realistically can better fit the dose-toxicity curve. Shu and O'Quigley^[9] point out that the two-parameter CRM estimates can be inconsistent and they recommend using a one-parameter CRM model.

Researchers have proposed and investigated early stopping rules for a model-based design. O'Quigley and Reiner, Zohar and Chevret, and Whitehead and Williamson^[19–20,18] describe stopping rules for Bayesian dose-finding studies.

Interval Designs

Interval designs are developed to have straightforward dose-level decision rules while incorporating model-based concepts. These designs combine the aspects of rule-based and model-based designs and dose-find using TPIs. Like rule-based designs, the interval designs dose-find by making up and down dose-level decisions. Like model-based designs, the aspects of the decision rules are based on Bayesian modeling. A useful interval design is the modified TPI (mTPI) design. This design is described next in detail; additional interval designs are referenced.

Modified Toxicity Probability Interval Ji et al.^[21] propose the mTPI, a modified design from the method described by Ji et al.^[22] The goal of the mTPI is to select a dose level with a high probability of having a toxicity rate within the target toxicity probability interval (TPI). The target TPI is defined during study design. A common target TPI is 0.20–0.35, representing a 20%–35% probability of toxicity.

The mTPI design recommends dose-level decisions using three predefined intervals and a statistic called the unit probability mass (UPM). The UPM is estimated using a Bayesian model.

Interval Definitions

- **Target TPI:** the target range on toxicity rate for a dose level (e.g., 0.20–0.35)
- **Underdosing TPI:** The range on toxicity rate for a dose level that may indicate suboptimal efficacy (e.g., toxicity rate from 0 to 0.20)
- **Overdosing TPI:** The range on toxicity rate for a dose level that indicates excessive toxicity (e.g., 0.35–1)

Unit Probability Mass

- For a dose level of interest, the UPM is the probability that the toxicity rate is within the interval of interest divided by the length of the interval.

Bayesian Model

- p_i represents the probability of toxicity at dose level i : A uniform prior distribution is assumed for each p_i . Accumulating data at dose level i are used to update posterior distribution for p_i .
- Define penalties for each possible decision and derive expected loss:
Decisions: escalate dose level, expand dose level, and de-escalate dose level
Ji et al. propose interval-based penalties in which minimization of expected loss corresponds to the highest UPM.

- Create a separate model for each p_i ; only data from the corresponding dose level i are used to update model of p_i . The study design lists planned dose levels. The initial cohort of subjects is treated at the lowest planned dose level. The mTPI dose-finding algorithm proceeds as follows:
- For the current dose level, update the Bayesian model. The updated Bayesian model will include data from the most recent cohort, applicable data from prior cohorts where subjects are treated at the current dose level and the Bayesian prior.
- For the current dose level, estimate the UPM for each interval and make dose-level recommendations for the next cohort.
De-escalate dose level: Overdose TPI has the highest UPM.
Repeat current dose level: Target TPI has the highest UPM.
Escalate dose level: Underdose TPI has the highest UPM.
- Determine if the current dose level is unacceptable. If overdose TPI has the highest UPM, the current dose level and any higher dose levels are excluded from future consideration.
- The study continues until one of the following exists:
Maximum enrollment is achieved.
All dose levels are unacceptable.

The sample size for an mTPI design is adaptive and depends on the dose level where toxicity is observed in accordance with planned dose levels. Designs that aggressively start at a high dose level will likely observe early toxicity and, therefore, identify the MTD with a minimal number of subjects (e.g., 9–12 subjects). Designs that start at a low dose with many planned dose levels due to cautious dose escalation will have larger sample sizes (e.g., 30 subjects).

Other Interval Designs Additional interval designs have also been proposed. Liu and Yuan^[23] propose the Bayesian optimal interval (BOIN) design. BOIN minimizes decision error in dose-finding trials with decision errors by optimizing the width of the target, and underdosing and overdosing TPIs. Also see the works of Ivanova et al.^[24] and Oron et al.^[24,25]

Designs Based on Ordinal Toxicity

Dose-finding study designs describe algorithms that optimize dose level using specifically defined safety endpoints, such as DLT. In practice, clinicians evaluate all available safety information including multiple safety endpoints when determining whether to follow the dose-finding algorithm. For example, the severity or grade of a toxicity is an important factor that the clinicians evaluate during review of safety data. To incorporate toxicity grade in

dose-finding designs, researchers have proposed methods to utilize ordinal toxicity information.

Meter et al.^[26] describe an extension of the CRM method for dose finding using ordinal toxicity. They propose a proportional odds (PO) model for the relationship between dose and ordinal toxicity. In this model, the intercept differs for each toxicity grade, but the relationship between increasing dose and increasing incidence of toxicity is the same for each toxicity grade. Maximum likelihood is used to estimate the parameters of interest with pseudo data used to stabilize the model. Meter et al. suggest that the pseudo data may be down-weighted or eliminated as enough actual data are collected to allow model stabilization. Additionally, Meter et al.^[27] describe an extension to the CRM method using a continuation ratio (CR) model. Doussau et al.^[28] propose a dose-finding model for longitudinal graded toxicity. Nebiyu Bekele et al.^[29] propose a dose-finding model using average toxicity score.

Designs Based on Time to First Toxicity

Dose-finding studies in oncology usually prespecify the observation period for toxicity. Often, toxicity that occurs after this observation period is not formally evaluated in dose-finding algorithms. Practically, clinicians do take into account late-onset toxicity when making dose recommendations. Researchers have developed dose-finding methodologies using time to first toxicity, an endpoint that can formally include information from subjects with incomplete follow-up and information from late-onset toxicity.

Cheung and Chappell^[30] extend the CRM method to incorporate time-to-event endpoints, a methodology that they refer to as time-to-event CRM (TTE-CRM). TTE-CRM utilizes information from early dropouts through weighted estimation. Subjects who complete the required observation period receive full weight in estimating the dose-toxicity relationship, whereas early dropouts have reduced weight. This weighting function assumes uniform distribution of time to toxicity over the observation period. Additional weight functions could also be used. Braun^[31] proposes a weight function in TTE-CRM that is a function of dose and allows timing of toxicity to vary with dose intensity. Yuan and Yin^[32] propose a methodology to jointly model time-to-event efficacy and toxicity. Polley^[33] proposes practical modifications to TTE-CRM. Wages et al.^[34] evaluate TTE-CRM in the presence of partial orders.

Designs That Optimize Dose Level and Schedule

The dose cycle frequency and the number of dose cycles can impact toxicity and efficacy. Oncology therapeutics typically have had breaks from dosing to allow patients to recover but the optimal length of this recovery period is not always obvious. A number of researchers have proposed methods to dose-find using both the dose level and the dose schedule.

Braun et al.^[35] propose a method to optimize dose level and dosing schedule. They propose modeling the hazard of toxicity so the overall probability of toxicity for an individual subject is a function of the dose level and the number and timing of doses received. They propose a triangular hazard that accounts for both dose level and follow-up time. Li et al.^[36] propose a methodology to optimize dose level and dose schedule based on toxicity and efficacy endpoints. They propose an algorithm to identify the dose level and dosing schedule with high probability of having both acceptable efficacy and acceptable toxicity. Thall et al.^[37] develop a methodology that includes two stages to adaptively optimize dose level and dosing schedule with the first stage randomizing subjects to a dosing schedule and the second stage using accumulating data to optimize dose and dosing schedule. Lee et al.^[38] develop a methodology to modify an individual's cycle 2 of treatment based on the results of cycle 1 dose level and outcome; decisions use the individual subject's cycle 1 data and data from other subjects on study. Some additional research in optimizing dose level and dose schedule can be found in the works of Zhang and Braun^[39] and Guo et al.^[40]

Discussion and Recommendations

The merits and limitations between algorithm-based designs (e.g., 3+3 design) and model-based designs are summarized in [Tables 1a](#) and [1b](#). The 3+3 design remains the most common design utilized to identify the MTD. Ji and Wang^[41] point out the popularity of the 3+3 design results from "...its simplicity (no computer program is required), transparency, and costless implementation in practice." Despite its popularity, the 3+3 design has some important limitations. The 3+3 design generally underperforms model-based designs in terms of operating characteristics such as accuracy in identifying the MTD and the percentage of Phase I subjects treated near the MTD.^[42–44] The 3+3 design also has a fixed toxicity limit of 33% which may not be ideal for certain drugs or indications. For example, the acceptable toxicity rate may be well below 33% in an indication with many treatment options and a long-expected survival. In addition, the 3+3 design is memoryless and does not utilize prior dose-level data when making dose recommendations. Finally, the inflexible decision rules for the 3+3 design can lead to operational inefficiency as decisions must be made using an exact number of evaluable subjects; these inflexible rules can slow enrollment and lead to study delays due to replacement of subjects. Many designs have been developed to overcome these deficiencies of the 3+3 design.

When resources are available to build a model, a model-based design such as the BLRM should be considered. As mentioned in Section "Model-Based Designs," researchers have shown good operating characteristics for model-based designs especially when compared to the 3+3 design. Model-based designs allow flexibility in targeting

Table 1a Merits of algorithm-based designs (e.g., 3+3 design) compared to potential limitations of model-based designs

Merits of algorithm-based design	Limitations of model-based design
1. Study executed without review of statistical output 2. Common use reduces up-front efforts to justify design features to review bodies (e.g., regulatory agencies) 3. Memoryless feature allows design to overcome misclassification of disease-related adverse event as a DLT 4. Insensitive to deviations from assumed dose–toxicity model	1. Study execution requires regular statistical support to generate statistical output 2. Operating characteristics required to justify design features to review bodies 3. Misclassification of disease-related adverse events as DLT difficult to remedy 4. Deviations from assumed dose–toxicity model can lead to bias in estimation of MTD

Table 1b Merits of model-based designs compared to potential limitations of algorithm-based designs (e.g., 3+3 design)

Merits of Model-Based Design	Limitation of Algorithm-Based Design
1. Flexibility in targeting toxicity rate 2. Flexibility in cohort sample size and open enrollment (e.g., two to four subjects per cohort) can reduce study execution delays due to subject replacement 3. Compared to 3+3 design, superior accuracy in identifying MTD^[42–44] 4. Facilitates up-front discussion regarding specifics of risk–benefit of a treatment in a particular disease indication. Increased scientific exchange allows for customization of study design.	1. 3+3 design does not have flexibility in targeting toxicity rate (less common algorithm-based designs can modify the target toxicity rate) 2. Strict decision rules based on fixed sample sizes often result in study execution delays due to subject replacement 3. Compared to model-based designs, inferior accuracy in identifying MTD^[42–44] 4. Standard approach can limit scientific exchange

a toxicity rate that allows customization of dose finding to the drug and indication. Model-based designs also incorporate data from prior dose levels when making dose-level recommendations. Additionally, model-based designs may improve dose-finding decisions by aiding communication between key decision makers. Finally, an important benefit of the model-based design is operational efficiency. In particular, model-based designs easily incorporate flexible cohort sizes (e.g., two to four subjects per cohort), which can speed up enrollment and reduce study delays due to replacement of subjects.

When resources are not available to build a model, there are good design options that overcome some of the shortcomings of the 3+3 design. For example, the mTPI interval design is simple and transparent. The mTPI design can be planned using an easy-to-use Excel tool. The mTPI has flexibility in modifying the target TPI which allows customization that meets the specific needs of an oncology drug and indication. The rule-based, up and down designs described by Ivanova et al.^[5] are also flexible enough to modify the target toxicity rate.

Model-based designs may also have dose-finding performance issues. When the actual dose–toxicity relationship deviates from the assumed dose–toxicity model, model-based approaches can make illogical dose-level recommendation (e.g., recommend dose escalation even though significant toxicity is observed at current dose level). As discussed previously, the two-parameter model can lead to erratic dose recommendations early on in the study and at small sample sizes. The choice of prior can impact early dose recommendations when actual observed data are minimal; Oron and Hoff^[45] describe

examples of small-sample behavior in Phase I cancer trials. Iasonos and O’Quigley^[17] note the circumstances where the one-parameter CRM model will underestimate the dose–toxicity relationship at higher dose levels when there is a run-in of safe lower dose. When considering a model-based approach, the researcher should execute clinical trial simulations in part to identify potential dose-finding performance issues.

DESIGNS TO IDENTIFY THE RECOMMENDED PHASE II DOSE

It is common in Phase I studies to have a primary objective of identifying the maximum tolerated dose and/or recommended Phase II dose (RP2D). This objective acknowledges that the maximum tolerated dose may or may not be the recommended future dose. The perfect drug and dose level would cure the disease in 100% of patients with no adverse effects of concern. Recognizing that this is not likely the case, the researcher seeks a RP2D that appropriately balances the trade-off between efficacy and safety. Additionally, efficiency in dose finding can be obtained using all relevant safety, efficacy, biomarker, and pharmacodynamic information in Phase I clinical trials to recommend a dose level for Phase II clinical trials. Multiple methods and approaches have been proposed and evaluated for identifying the RP2D. We classify these methods into two categories: designs that balance the trade-off between toxicity and efficacy, and designs that incorporate safety, biomarker, and pharmacokinetic/pharmacodynamic data.

Sections “Designs That Balance Toxicity and Efficacy” and “Designs That Incorporate Biomarker/Pharmacodynamic Data” summarize designs to identify the RP2D. Section “Discussion and Recommendations” provides recommendations regarding the use of these designs to improve dose finding.

Designs That Balance Toxicity and Efficacy

Designs that balance the trade-off between toxicity and efficacy seek to identify a dose level that maximizes efficacy while maintaining an appropriate safety profile. A useful trade-off design is proposed by Thall and Cook (TC).^[46] The TC design is described next in detail; additional trade-off designs are referenced.

TC Trade-Off Design

TC design is a Bayesian approach to dose finding that aims to optimize the trade-off between toxicity and efficacy. A contour C defines the acceptable trade-off between toxicity and efficacy. Contour C is constructed using the following three inputs from the investigating clinicians:

1. The drug’s lowest level of efficacy allowable if the drug has no toxicity
Example: 0% DLT rate and 10% objective response rate (ORR)
2. The drug’s highest incidence of adverse events allowable if the drug is 100% effective
Example: 50% DLT rate and 100% ORR
3. One example of intermediate safety and efficacy
Example: 25% DLT rate and 35% ORR

A smoothing procedure identifies contour C where C includes each paired safety/efficacy value described in inputs 1–3. A dose level is acceptable if the safety/efficacy profile is at or better than the contour C. TC scores the safety/efficacy profile of a dose level of interest using the distance from contour C to the dose’s predicted safety/efficacy. Dose-level profiles on contour C are scored as zero. If a dose-level profile is better than profiles on contour C, then a larger distance from contour C leads to a higher positive profile score. If a dose-level profile is worse than profiles on contour C, then a larger distance from contour C leads to a more negative score. TC uses an algorithm to identify a dose level with the maximum score, where the maximum score indicates the maximum risk/benefit. Fig. 1 shows an example contour C.

Key features of the dose-finding algorithm are as follows:

- Jointly model the efficacy/safety profile using Bayesian model.
- Prespecify dose levels of interest.

Fig. 1 Example of contour C in the TC trade-off design. Contour C defines the acceptable trade-off between toxicity and efficacy. Contour C has the red dots with the dots representing the three inputs used to derive C. The other contours represent safety/efficacy profiles which are inferior (closer to upper left) or superior (closer to bottom right) to contour C

- After each cohort, update Bayesian model and predict the efficacy and safety for each dose level of interest.
- Stop study if no dose levels are acceptable (or maximum sample size is reached).
- If at least one dose level is acceptable, treat the next cohort of subjects at the dose level with the maximum score.

The maximum sample size (e.g., $n = 60$ subjects) and other design features are chosen a priori for the trade-off design. Simulations should be done to evaluate the impact of these design features on operating characteristics. Thall et al.^[47] provide additional practical advice on how to implement this trade-off contour design.

Other Trade-Off Designs

Thall and Russell (TR)^[48] propose a Bayesian adaptive design with the goal of dose finding using trinomial outcomes (“no efficacy and no toxicity,” “efficacy and no toxicity,” “no efficacy and toxicity”), using a PO model. Braun^[49] extends the CRM to incorporate bivariate endpoints, called the bivariate CRM. Fan and Chaloner^[50] use a CR model that is more flexible than the PO model. Zhang et al.^[51] propose an approach similar to TR but using the CR model and making modifications to the dose selection criteria and stopping rules. Yin et al.^[52] develop an approach of dose finding using efficacy and toxicity that does not require specifying the parametric functional form of the dose–response curve.

Mandrekar et al.^[53] review and offer practical solutions to challenges that arise with executing a dose-finding study incorporating both efficacy/toxicity. Zhong et al.^[54] develop an approach that also incorporates a surrogate for efficacy. Yuan and Yin^[55] propose a method using time to toxicity and efficacy endpoints. Lee et al.^[56] propose a methodology with the goal to adaptively select dose to maximize risk–benefit for every subject treated on study. Dragalin and Fedorov^[57] propose a penalized D-optimal design with the penalty functioning to help balance out the interests of the individual with the interest of future patients. Dragalin et al.^[58] propose a two-stage design with information from stage 1 informing dose allocation of stage 2; stage 2 allocates patients to dose levels chosen to minimize the variance of the estimator for optimal dose.

Designs That Incorporate Biomarker/Pharmacodynamic Data

Continuous measures of efficacy and safety may be incorporated to improve dose finding. Biomarker and pharmacokinetic/pharmacodynamic data may inform dosing.^[59] Researchers have proposed methods to incorporate this information in dose finding.

Nebiyou Bekele and Shen^[60] propose jointly modeling toxicity and biomarker expression in a dose-finding trial. Ivanova and Kim^[61] generalize a methodology to dose-find using various combinations of dichotomous, continuous, or ordinal endpoints. Hirakawa,^[62] Padmanabhan et al.,^[63] and Yeung et al.^[64] propose a methodology to dose-find using correlated binary and continuous responses. Thall et al.^[65] propose a methodology to optimize the concentration and bolus drug delivery. Fedorov et al.^[66] discuss optimal dose-finding designs with correlated continuous and discrete responses. Zhong et al.^[67] develop a methodology to dose-find using toxicity, efficacy, and surrogate efficacy.

Discussion and Recommendations

Restricting dose finding in oncology to only Phase I clinical trials is a practice that can lead to suboptimal dosing of patients. We recommend that dose-finding activities continue past Phase I and that a Phase I/II design such as the TC design be strongly considered. Historically, Phase I trial identifies the MTD and Phase II accumulates additional safety data and screens for efficacy; Phase II data have not typically been used to reevaluate the MTD. The limited data in Phase I leads to uncertainty in estimation of MTD regardless of study design.^[42] Safety data from Phase II can be used to improve the estimate of the MTD. The TC design can utilize Phase II data to improve MTD estimation as well as utilize Phase I data along with Phase II data to improve efficacy estimation. Additionally, the convention of dosing at the MTD can ignore the important benefit–risk trade-offs. The level of acceptable toxicity may depend on the level of efficacy, the severity

and manageability of the toxicity, the disease prognosis, and the availability of alternative therapies. Continuing to dose-find past Phase I allows improved refinement in the understanding of a drug's benefit–risk.

Dose finding can be improved by more frequently modeling pharmacokinetics and/or dose level with pharmacodynamics, adverse events, safety labs, and efficacy endpoints. Typical dose-finding studies simplify the dose-finding problem by simplifying the dose-finding endpoints. In practice, the deciding clinicians evaluate a totality of data when making decisions. The grade of adverse events and the timing/duration of the event are considered. Safety labs such as platelet counts over time and in relation to pharmacokinetics are considered. Pharmacodynamics and efficacy data may be important. Developing exploratory models of these relationships and reviewing these models with clinicians will aid communication and decision-making.

DESIGNS TO IDENTIFY THE COMBINATION MTD

Treatment regimens with two or more active agents often show synergy in efficacy. An effective drug in monotherapy is usually evaluated in combination with other agents. With two agents, the identification of the maximum tolerated dose is a two-dimensional problem. A useful design to identify the combination MTD is the partial order CRM (POCRM) proposed by Wages et al.^[68] This design is described next in detail; additional combination MTD designs are referenced.

Partial Order CRM

POCRM reduces the two-dimensional dose finding into one-dimensional problem by using the concept of partial orders and model selection. Using partial orders, POCRM categorizes plausible models that order the treatment combinations from least toxic to most toxic. To illustrate, here is a simple example of partial orders.

Example of Partial Orders

The following treatment combinations are under investigation:

- Combination 1: Drug A at 100mg and Drug B at 100mg
- Combination 2: Drug A at 100mg and Drug B at 200mg
- Combination 3: Drug A at 200mg and Drug B at 100mg
- Combination 4: Drug A at 200mg and Drug B at 200mg

The following are partial orders:

- Combination 1 is less toxic than Combinations 2, 3, and 4.
- Combination 4 is more toxic than Combinations 1, 2, and 3.

Given the known partial orders and the unknown relative toxicity between Combinations 2 and 3, there are two plausible models ordered from least toxic to most toxic:

- Model 1: 1, 2, 3, 4
- Model 2: 1, 3, 2, 4

POCRM assigns a prior probability to each model. The model with the highest prior probability is selected as the working model for dose finding. In the absence of data or with limited data, the working model may be randomly selected. Using the selected working model, a one-dimension CRM is used for dose finding. As data accumulate, a different working model may be selected based on posterior model probabilities.

The maximum sample size (e.g., $n = 36$ subjects) and other design features are chosen a priori for the POCRM design. Simulations should be done to evaluate the impact of these design features on operating characteristics. Wages and Conaway^[69] give additional practical guidance on implementing POCRM.

OTHER COMBINATION MTD DESIGNS

Thall et al.^[70] propose a six-parameter power-logit function for the joint distribution. Yin and Yuan^[71] propose a joint model that uses a copula. Bailey et al.^[72] propose a methodology to use logistic regression with covariates. Ivanova and Wang^[73] propose an “up-and-down” method. Additional methodologies are described by Conaway et al.,^[74] Huang et al.,^[75] Yin and Yuan,^[76] Braun and Wang,^[77] Wages and Conaway,^[78] Hirakawa et al.,^[79] Mander and Sweeting,^[80] Riviere and Karelle,^[81] and Jin et al.^[82]

Discussion and Recommendations

We recommend the POCRM design for combination studies. In particular, POCRM should be considered to dose-find when a new drug is combined with an established drug. Since the established drug has a well-described efficacy profile, lowering the dose level of the established drug is often not considered. This practice may miss out on finding a dosing combination that optimizes benefit–risk. For example, the optimal benefit–risk for drug combinations may be at moderate dose levels for both drugs including using a dose level for the established drug that is below the label prescribed level. POCRM can easily interrogate multiple dose levels, even for the established drugs. POCRM leverages the well-understood CRM methodology and facilitates communication among the statistician, the clinician, and other scientists. POCRM may get complicated if partial orders lead to a large number of possible orderings. Practically, the number of orderings likely can be reduced to a smaller set of plausible orderings. The drugs of interest will have existing preclinical and clinical data to aid planning of

the combination study. Utilizing these data and good communication among the statistician, the clinician, and other scientists should allow the identification of a reasonable number of plausible orders to investigate in POCRM.

RECENT TRENDS IN DOSE FINDING

Utilization of dose expansion data in Phase I has received attention recently. It has become common practice in FIH oncology studies to add a dose expansion part with an additional 10–20 subjects. After the Phase I study identifies an MTD, the purpose of dose expansion is to gain additional safety data and preliminary efficacy data at the MTD. Iasonos and O’Quigley^[83–85] propose a methodology to utilize dose expansion data to update the estimate of the MTD. Additionally, they present a methodology to continue monitoring safety while assessing efficacy and exploring patient subsets with enhanced responsiveness to treatment.

The concept of the maximum tolerated contour (MTC) has been proposed for recent combination dose-finding methodologies. The contour represents the pairs of dose levels between Agent A and Agent B that have equal probability of toxicity, with MTC being the pairs of dose levels with the target toxicity probability. Researchers publishing methodologies for dose finding in combinations studies using MTC are Wages,^[86] Zhang and Yuan,^[87] and Mander and Sweeting.^[88]

Dose finding utilizing information from different subsets (e.g., ethnic population or tumor types) has been the topic of recent methodologies. Liu et al.^[89] discuss the bridging information across ethnic populations. Broglio et al.^[90] discuss the sharing of information between different patient populations such as different tumor types. Quintana^[91] discusses optimizing dose and schedule using data from different tumor types. Conaway and Wages^[92] use ordered groups to identify the MTDs where groups are ordered by drug tolerability. Wages et al.^[93] and Salter et al.^[94] discuss dose finding in heterogeneous groups.

Personalized dose finding has recently been further investigated. Chen et al.^[95] seek to optimize the individual dosing rule using weighted learning. Zhou et al.^[96] propose a residual weighted learning to estimate individual treatment rules. Guo and Yuan^[97] investigate a biomarker-driven personalized dose finding. Mao and Cheung^[98] propose a sequential design to aid individualized dose finding.

Abstract

Clinical development of new therapies is a complex process that requires considerable time and resources. The phase 3 trial failure rate is particularly high in oncology (oncology new drug application (NDA) approval rate is only 40%). In order to streamline and expedite the drug development for oncology and more efficiently identify the right population with right regimen for the patients around the world, innovated study designs should be implemented for drug developments including oncology trials. Adaptive design provides a more flexible framework for clinical development that can help increase the efficiency for use of available resources. Increasingly, drug makers are interested in using adaptive design trials to accelerate clinical development and speed new medicines to patients in need. Clinical trials using a biomarker strategy may result in smaller study sizes and higher probability of trial success with the right target patient population which in turn reduces development risk and generates higher return on investment. Multi-Regional Clinical Trials (MRCT) is a more efficient strategy to expedite global clinical development and facilitate drug registration globally. We provide some commonly used design strategies for oncology drug development, with main focus on adaptive design, biomarker-driven study design, and study design considerations for MRCT. We believe that adaptive design, biomarker utilization, and MRCT are three integral parts of a clinical development strategy for oncology drug.

Keywords: Oncology trial; Adaptive design; Biomarker driven design; Multi-Regional Clinical Trials (MRCT); Type I error rate.

INTRODUCTION

Clinical development of new therapies is a complex process that requires considerable time and resources. The phase 3 trial failure rate is particularly high in oncology (oncology new drug application (NDA) approval rate is only 40%). Gan et al.^[1] reviewed 235 published phase 3 randomized clinical trials (RCTs) for oncology and reported 62.5% of trials did not achieve statistical significant results. There is clearly a need for more innovated study designs to improve the success rate of oncology drugs.

Adaptive design provides a more flexible framework for clinical development that can help increase the efficiency for use of available resources. Adaptive design can be used to improve drug development process across different stages. For exploratory trials, the use of adaptive design can help the sponsor make better decisions to reduce phase 3 failure rate, potentially expose fewer patients to less effective treatment for unnecessary toxicity, and shorten

clinical development timeline by combining trials from different stages. Adaptive design in the pivotal trial setting allows the sponsor to further improve the design using interim trial results without losing statistical validity and integrity of the trial.

Traditional RCTs focus on the average treatment effect in the overall population by testing the treatment in an unselected or untargeted population (i.e., all-comer design). However, many new anticancer agents are molecularly targeted and might only benefit a subgroup of patients. Efficient development of new anticancer drugs might, therefore, need to use clinical trial designs that take into account response heterogeneity between different subgroups. In oncology, predicted biomarkers are used to develop classifier to identify patients who are more likely to respond to the investigational therapies. For a well-established biomarker, a common strategy is to enroll and demonstrate treatment benefit in marker-positive (denoted as g+) patients only (i.e., enrichment design). However,

this study design will lose the opportunity for studying marker-negative (denoted as g-) patients and thus overall population in case the drug works for the entire population. In addition to all-comer design and enrichment design for clinical trial with a well-established biomarker, some other more efficient biomarker-driven designs are available to enhance the power of selecting the right therapy for the right patient. Thus, different type of biomarker-driven designs and enrollment strategies could be considered based on different degrees of confidence in biomarkers and disease prevalence.

With the increase of globalization of drug development, more and more pharmaceutical industries are conducting Multi-Regional clinical trials (MRCT) to support a new drug's safety and efficacy across different populations. Commonly, it takes a few years or even more than a decade to develop a new oncology drug and make it available to patients. If the population is not included in the original study, "bridging study" is usually required in order to gain approval in the emerging market, which causes the "drug lag" problem. A carefully designed MRCT could be used to support the new drug's approval in different regions/countries simultaneously. By conducting MRCT for oncology drug development, we can bring new effective drug to patients globally as fast as possible. It also provides a pathway for a regulatory agency to evaluate the drug's safety and efficacy profile based not only on the overall patient population but also the local region.

In this entry, we provide some commonly used design strategies for oncology drug development, with main focus on adaptive design, biomarker-driven study design, and study design considerations for MRCT.

ADAPTIVE STRATEGIES FOR ONCOLOGY TRIALS

Sample size reestimation (SSR) design is one of the most commonly used adaptive designs. The idea is to use interim analysis results to modify the final sample size of the trial. Besides SSR adaptive design, group sequential design and drop-the-loser design are increasingly used in oncology trials. In group sequential design, a trial can be stopped prematurely if there are safety or efficacy issues and depending upon the results of the interim analysis, additional modifications can be made. In drop-the-loser design, the subjects detected to have received inferior treatments at the interim analysis can be dropped out. Based on the findings of the interim analysis, additional treatment arms can also be added at this stage (Chang and Wang^[2]). This design is useful in phase II or phase II/III clinical development with same study objective and endpoint between phase II and phase III, especially when there are uncertainties regarding the dose levels. Typically, drop-the-loser design is a two-stage design. At the end of the first stage, the inferior arms will be dropped based on

some prespecified criteria. The winners will then proceed to the next stage. Some prefer to term these designs as pick-the-winner designs (Mahajan and Gupta^[3]). Chow and Chang^[4] summarized most of the commonly used adaptive designs for clinical trials. In this section, we mainly focus on the SSR design; adaptive design strategies with established biomarker will be introduced and discussed in next section.

SSR Design

If only blinded results (based on aggregate data without unblinding treatment arms) are used, there is generally no impact on the integrity of the final study results. For a typical time-to-event endpoint in oncology trials, increasing the number of patients enrolled in order to achieve the prespecified event driven analysis is generally accepted by regulatory agencies. This is well reflected in their guidances (Food and Drug Administration, FDA, Guidance for Industry:^[5] Adaptive design clinical trials for drugs and biologics; FDA Guidance for Industry and Food and Drug Administration Staff:^[6] Adaptive design for medical device clinical studies; European Medicines Agency (EMA) Reflection paper on methodological issues in confirmatory clinical trials planned with an adaptive design^[7]).

On the other hand, using unblinded interim results for sample size, reestimation has gained popularity in practice due to several attractive features, especially when there is a greater uncertainty about the treatment effect. It generally requires smaller upfront investment compared to group sequential design or fixed design. With group sequential design or fixed design, treatment effect size is often conservatively assumed which leads to a larger study size to begin with. With this design, the original study size is generally smaller with an optimistic assumption on the treatment effect size.^[8] If the optimistic assumption turns out to be true, the new drug can be brought to patients quicker with a smaller trial. On the other hand, if the original assumption is too optimistic, this design allows for sample size increase to improve the probability of success.

The downside of the design is the potential type I error inflation. As shown by Proschan and Hunsberger,^[9] certain adaptation rules can inflate the type I error for this type of design by two times or more. Multiple papers have proposed ways to control the type I error in this setting. Three main approaches have been observed in the literature.

- One is to construct a combination test statistic by combining the test statistics (or p values) from separate stages: Bauer and Kohne^[10] proposed Fisher's product; Lehmacher and Wassmer^[11] and Cui, Hung, and Wang,^[12] proposed weighted sum of test statistics with fixed weights. This type of approach is very attractive because there is no restriction on the adaptations as long as the conditional invariance principle (Brannath,

Koenig, and Bauer^[13]) is followed. However, it is criticized for not satisfying one patient one vote rule.

- The second way is called the conditional error function approach (Proschan and Hunsberger^[9]) where this function is predefined and integrates (with respect to the interim results) to the prespecified level of type I error rate. The key idea is that as long as the adapted procedure yields the same value as the conditional error probability given interim results, the overall type I error is controlled by definition. A natural choice of the conditional error function is the one based on the planned design (Schäfer and Müller,^[14] Müller and Schäfer,^[15] and Müller and Schäfer^[16]). Once the conditional error probability is determined based on the interim results, a new critical value can be calculated to preserve the same conditional error probability (or equivalently one can use the conditional error probability as the new “alpha” for the next stage of the trial). A potential interpretation problem can rise if the calculated new critical value is more liberal than the conventional cutoff.
- The combination test and conditional error approach appear to be different in terms of implementation. However, if one focuses on a typical rejection rule comparing a test statistic with a critical value, it is easy to observe that each method is modifying one side of the inequality that should be equivalent mathematically as shown in the study by Proschan.^[17]
- The third approach is to leave the conventional test statistic and critical value unchanged but to modify the adaptation rule to maintain the type I error at the desired level (Brannath, Koenig, and Bauer^[13]). This approach is practically attractive as it does not require modification of the rejection rule. Two of the most commonly used adaptation rule is shown in Fig. 1, where x-axis is the conditional power at interim analysis and y-axis is the ratio of final adapted sample size to the original planned final sample size. For ways to modify

the adaptation rule in order to maintain overall type I error, the studies by Mehta and Pocock^[18] and Liu and Hu^[19] are referred.

Specific Issues with Time-to-Event Endpoint

Time-to-event endpoint is commonly used for oncology trials, and there are some specific issues that need to be considered. In a typical 2 stage SSR design, analysis timing is typically driven by the total number of events. If we calculate 1st stage test statistic based on patients enrolled before interim analysis and 2nd stage test statistic based on patients who are enrolled after the interim analysis, then data on those patients who are enrolled before interim and experience event between interim and final analysis will be lost. Fortunately, the increments between the 1st stage test statistic and the test statistic based on all enrolled patients at final analysis are stochastically independent as was shown for the classical group sequential designs. Specifically, assume d_1 is the total interim events and d_2^* is the final adapted total events. Let LR_k denotes the log-rank test statistic at stage k based on the cumulative data up to that stage. Then the incremental test statistic can be calculated by:

$$\tilde{Z}_2^* = \frac{\sqrt{d_2^*} LR_2 - \sqrt{d_1} LR_1}{\sqrt{d_2^* - d_1}} \quad (1)$$

Wassmer^[20] proposed an inverse normal combination test statistic that uses the independent increments structure of the log-rank test statistic. This method allows for many kinds of design modifications during the trial. Lehmacher and Wassmer^[11] also proposed a repeated confidence interval based on the combination of the independent increments of the log-rank test statistic.

It was shown that combination test and conditional error approaches are ways to handle adaptations at interim

Fig. 1 Different adaptation rules for SSR design, n_2^* and n_2 are the final adaptive sample size and the original planned sample size, respectively

without alpha penalty. However, there are pitfalls in the time-to-event endpoint setting where simple application of these methods may still result in type I error inflation. As pointed out by Bauer and Posch,^[21] if the interim decision uses a surrogate endpoint such as progression free survival (PFS) that is correlated with survival, then for patients who have progressed but still alive at the interim and died before the final analysis, they will contribute to the 2nd stage overall survival (OS) event analysis (not merely determining the sample size). This violates the independence condition (between the first data and second stage data), thus also the conditional invariance principle for most methods (such as the combination test) to control type I error rate.

In order to address this issue, Jenkins, Stone, and Jennison^[22] proposed several alternative testing strategies for OS at final analysis in the more complicated subgroup selection setting with PFS as the surrogate endpoint. One preferred strategy that is proven to control overall type I error is to use the weighted test statistics for OS at final analysis (FA). The key is to determine what data for which set of patients go into the 1st and 2nd stage test statistic, respectively. The patients will be separated into two stages depending on whether they were used for PFS analysis (including patients that did not experience a PFS event) at interim. The log-rank test statistics for OS data at FA among the 1st (2nd) stage patients then forms the 1st (2nd) stage test statistic. This way of separating patients is to ensure independence between the two stage test statistics.

BIOMARKER-DRIVEN DESIGN WITH ESTABLISHED BIOMARKERS

We assume that a biomarker has been established through advances in the scientific and medical field or suggested by early phase data. Adopting the biomarker into the phase III trial design can potentially save a trial when treatment does not show expected efficacy in the overall population. Prospectively planning the biomarker testing strategy can potentially reduce the number of trials required (as retrospective findings usually requires another confirmatory trial) and thus shorten the development timeline and bring the effective treatment to the right subset of patients sooner.

We will first discuss “Phase III Fixed Design Strategy” where only final analysis is performed and then “Phase III Adaptive Design Strategy” where an interim analysis is planned to guide the design for the 2nd stage of the trial. These two biomarker strategies are based on a baseline biomarker where the marker status is obtained before receiving treatment.

Phase III Fixed Design Strategy

The fixed design strategy refers to a design with one final analysis. The main idea behind all the methods proposed in this section is to formally test both overall population

and biomarker-defined subgroup(s). The initial thinking in the literature (e.g., the study by Wang, O’Neill, and Hung^[23]) was to include the testing of g+ patients in addition to the overall population as g+ subgroup is assumed to have a much larger treatment effect. In terms of multiplicity adjustment, methods such as fixed sequence testing (either overall test followed by g+ subgroup or testing g+ subgroup followed by the overall test), alpha split, Hochberg method, and stepdown method incorporating correlation between the subgroup and the overall population are applicable in this setting. Which method to use depends on the degree of confidence in the biomarker (in terms of the differential treatment effect between g+ and g– subgroups) as well as the prevalence of the subgroup.

The following illustrates a few commonly seen designs with different enrollment strategies and testing procedures.

Stratified Designs: Enroll Overall with Biomarker Stratification

A biomarker has strong credentials when evidence for the predictive ability of the biomarker is convincing enough to assume that the treatment is more likely to be effective (and is probably more effective) in the g+ than in the g– subgroup, but the evidence is not sufficiently compelling to rule out a clinically meaningful effect in g– patients. In this scenario, a biomarker-stratified trial design is a preferred option.

Biomarker-stratified designs randomly assign both g+ and g– patients to the treatments under investigation (Fig. 2). Similar to enrichment designs, the biomarker-stratified designs must include a definitive assessment of the treatment in the g+ subgroup. Several possible statistical testing strategies can be used in biomarker-stratified designs.

Testing Strategy 1: Test g+ and Overall Sequentially

First, the treatment effect is tested in g+ patients using significance level α (Fig. 3); if the results of this hypothesis test are significant, then the treatment effect is also tested in overall patients, using the same α value.

An alternative analysis approach is to test treatment effect in overall patients using significance level α first,

Fig. 2 Enrollment strategy for biomarker-stratified design

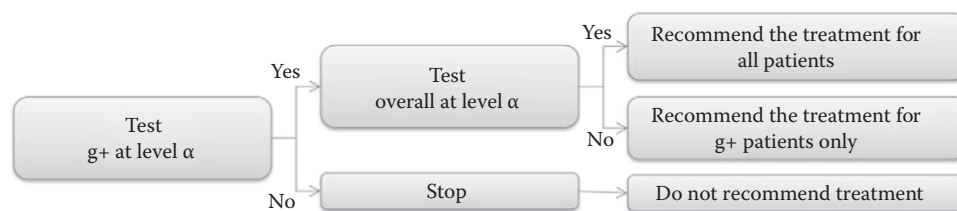

Fig. 3 Testing procedure for sequential g+ and overall design

if the results of this hypothesis test are significant, then the treatment effect is also tested in g+ patients, using the same α value.

Testing Strategy 2: Test g+ and Overall in Parallel

A parallel testing strategy with the biomarker subgroup-specific trial design is also possible; in the parallel version, testing of g+ subgroup and overall population is done simultaneously. However, to control the overall type I error rate of the design at level α , the parallel version requires allocating the overall α between the two tests, which makes statistical significance harder to achieve in the g+ subgroup.

Testing Strategy 3: Test g+ and g–

First, the treatment effect is tested in g+ patients using significance level α (Fig. 4); if the results of this hypothesis test are significant, then the treatment effect is also tested in g– patients, using the same α value.

A parallel testing strategy with the biomarker subgroup-specific trial design is also possible; in the parallel version, testing of the biomarker-positive and biomarker-negative subgroups is done simultaneously. Most of the multiple comparison procedure, e.g. Hochberg, Holm, Fall back, exhaustive Fall back, etc., needed to be used to control the overall type I error rate.

Usually, it is easier to claim statistical significant to test g+ and overall comparing to test g+ and g–. However, a key concern with the g+ and overall strategies is that when the benefit of the new therapy is restricted to the g+ patients, the design might inappropriately recommend the treatment for the g– subgroup, even though the treatment is ineffective in these patients. The overall efficacy could be highly driven by g+ subgroup, a statistically significant effect can still be observed in the overall population if its effect in the g+ patients is large enough even with no treatment effect in

the g– subgroup. So it seems logical to assess the treatment effect in this g– population after seeing a significant benefit in the g+ population. However, it is very challenging to achieve statistical significant in both g+ and g– subgroup due to reduced sample size in subgroup and smaller effect size in the g– subgroup by assumption in practice. The adaptive design described in the next section might be one of the solutions to conquer these challenges in which the ineffective subgroup will be dropped at interim and only the effective subgroup will continue to next stage and tested at the final analysis.

Testing Strategy 4: Test g+ and g– and Overall

The main reason for using a g+/overall population assessment strategy is that the test in the overall population allows implicit borrowing of information from the g+ subgroup in providing a treatment recommendation for the g– patients. In principle, this could be an attractive approach when the treatment effect is homogeneous across the biomarker-defined subgroups, as long as steps are taken to control the probability of incorrectly recommending the treatment for the g– patients if it does not work for them.

Unlike the g+/overall population strategy, this control is achieved by the Marker Sequential Test (MaST) design (Freidlin, Korn, and Gray^[24]). The MaST design (Fig. 5) incorporates analyses of g+ and g– subgroups as well as the overall population. First, the g+ subgroup is tested at a reduced significance level (α_1), which can be any value less than the desired overall significance level α of the trial. If the results of this test are significant, the g– subgroup is tested at significance level α . If the results in the g+ subgroup are not significant, the overall population is tested at significance level $\alpha - \alpha_1$. If this overall population test is significant, the treatment is recommended for the whole population; if this overall population test is not significant, the treatment is not recommended for any patients regardless of biomarker status.

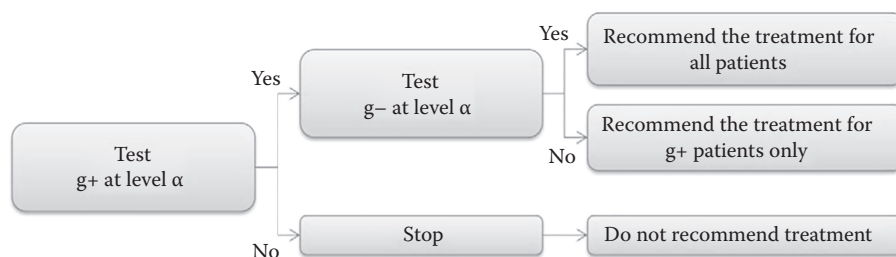

Fig. 4 Testing procedure for sequential g+ and g– design

Fig. 5 Testing procedure for MaST design

This strategy only tests the overall population when no significant effect is detected in the g+ subgroup; it reduces the risk of erroneously concluding that the treatment is beneficial in the overall population when positive findings in the overall group are driven by a benefit limited to g+ patients.

Modified Stratified Design: Selectively Enroll g+ Patients

As FDA guidance has explicitly requested to include g- patients in enrichment design, or the potential of overall treatment effect in all-comer population, an enrichment design that randomizes g+ patients only may not be sufficient. On the other hand, if an all-comer population is randomized, the efficiency associated with the enrichment trial design feature is then lost. It would become a challenge, particularly when g+ is a relatively small subpopulation that a large number of g- patients have to be enrolled into such a trial in order to be able to recruit a sufficient number of g+ patients.

In order to conquer these challenges, especially when the disease prevalence is low, modified stratified designs (Yang et al.^[25]) might be an option to solve these problems, which enroll all g+ patients, but selectively enroll g- patients as illustrated in Fig. 6.

Since the patients enrolled in this study design do not represent the real disease prevalence in overall population, the following weighted estimator could be used to estimate the treatment effect for overall population

$$\hat{\delta} = \hat{p}\hat{\delta}_+ + (1 - \hat{p})\hat{\delta}_- \quad (2)$$

Fig. 6 Enrollment strategy for modified stratified design

where $\hat{\delta}_+$ and $\hat{\delta}_-$ are estimators of treatment effects in g+ and g- subgroups, respectively; $\hat{p}$ is the proportion of g+ patients obtained at screening phase. Theoretically, most of the testing procedures described in the section of stratified designed can be applied to modified stratified design, e.g. sequential test (g+, overall), Hochberg, Holm, fall back, exhaustive fall back, etc.

Phase III Adaptive Design Strategy

For the illustration purpose, we mainly focus on two-stage adaptive design when the best possible patient population to study is uncertain. The adaptive design strategy incorporates two stages where an interim look is prospectively planned. At the end of stage 1 (i.e., interim analysis), the prespecified decision is to maintain the original study plan or to modify the plan in terms of recruitment and testing strategy at the final analysis. All issues discussed in the previous section on fixed design strategy still apply to this section. However, we will focus more on the differences in the decision rules at interim to guide design for the second stage of the trial.

General setting for the adaptive design is to evaluate efficacy in overall and predefined g+/- subgroup with interim adaptation in two aspects:

1. enroll overall or only g+
2. test overall with/without g+ or test g+ only at the FA

Several papers fall in this setting and have proposed different interim decision rules (Wang, O'Neill, Hung;^[23] Brannath et al.^[26] Jenkins, Stone, and Jennison;^[22] and Stallard et al.^[27]).

Two sets of interim decision rules are built to facilitate patient selection in stage 2 and determine the hypotheses to be tested at the final analysis. One rule, decision rule 1, is to evaluate the overall population, the predefined g+/- subgroups separately in terms of futility and efficacy. The other rule, decision rule 2, is to compare the relative difference in efficacy between the overall population and the subgroups to determine patient selection in stage 2, while using the same futility rule as decision rule 1. Both of these two decision rules can be rooted in treatment effect, condition power, and predictive power. These three

decision parameters have equivalent performance in making interim decisions.

For illustration purpose, treatment effect hazard ratio (HR) is used to describe the decision rules. The fundamental idea of decision rule 1 is similar to Brannath et al.^[26] Decision rule 1 directs a pivotal trial to proceed into stage 2 and the final analysis as below:

1. If $HR_o \geq c_1$ and $HR+ \geq c_2$ (overall bad, g+ bad), then stop for futility
2. If $HR_o \geq c_1$ and $HR+ < c_2$ (overall bad, g+ good), then enrich to g+ patients in stage 2 and test g+ only at final analyses
3. If $HR_o < c_1$ and $HR+ \geq c_2$ (overall good, g+ bad), then continue to enroll overall population in stage 2 and test overall at final analyses
4. If $HR_o < c_1$ and $HR+ < c_2$ and $HR- \geq c_3$ (overall and g+ good, g- bad), then enrich to g+ patients only in stage 2 and test g+ only at final analyses
5. If $HR_o < c_1$ and $HR+ < c_2$ and $HR- < c_3$ (consistent, overall, and g+/g- all good), then continue to enroll overall population in stage 2 and test both overall and g+ at final analyses

Decision rule 2 adopts the similar logic as Stallard et al.,^[27] which measures the absolute difference in efficacy effect size between the overall population and the g+ subgroup. Even though decision rule 2 does not explicitly evaluate consistency among the overall population and the g+/g- subgroups, the absolute difference implicitly indicate the consistency between the overall population and the g+ subgroup. A disadvantage of Stallard et al.^[27] is not to evaluate futility simultaneously for the overall population and the g+ subgroup. Decision rule 2 circumvents this problem by using the same futility boundary from decision rule 1. Decision rule 2 will drive the following logics for interim decision making:

1. If $HR_o \geq c_1$ and $HR+ \geq c_2$ (overall bad, g+ bad), then stop for futility
2. If $|HR_o - HR+| > \varepsilon$ and $HR_o \geq HR+$ (overall and g+ not close, g+ better), enrich to g+ in stage 2 and test g+ population only at final analyses
3. If $|HR_o - HR+| > \varepsilon$ and $HR_o \leq HR+$ (overall and g+ not close, overall better), then continue to enroll overall in stage 2 and test overall population at final analyses
4. If $|HR_o - HR+| < \varepsilon$ (overall and g+ close), then continue to enroll overall in stage 2 and test both overall and g+ population at final analyses

An essential element of SSR for adaptive design is also built into the internal adaptive design strategy. Conditional power could be used for SSR.

Enrichment to the g+ subgroup, interim analysis, and sample size reassessment all contribute to type I error inflation. Inverse normal combination test under closed

test procedure is used to strongly control family-wise type I error rate. Multiplicity control procedures such as Hochberg, Simes, Bonferroni, etc., can be used to obtain adjusted p value for the intersection hypothesis.

MULTI-REGIONAL CLINICAL TRIALS

There is an increasing trend to conduct MRCT for drug development in pharmaceuticals industry. A carefully designed MRCT could be used in supporting the new drug's approval in different regions simultaneously. The primary objective of an MRCT is to investigate the drug's overall efficacy across regions while also assessing the drug's performance in some specific regions. One of the statistical challenges in conducting MRCT is to ensure that overall efficacy can be adequately preserved in regions of interest. To evaluate the possibility of applying the overall results in a MRCT to the specific regions of interest, the Japanese Ministry of Health, Labour and Welfare (MHLW)^[28] proposed two methods for determining the needed number of Japanese subjects for establishing consistency of the treatment effect between the Japanese patients and others:

Method 1: The sample size needed for the Japanese patients in a MRCT was to satisfy:

$$P(D_i/D > \pi_i) > 1 - \beta' \quad (3)$$

where D_i and D are the estimated treatment effects from the group of Japanese patients and the entire patient population, respectively, π_i is the effect retention rate ≥ 0.5 , and β' is the type II error rate ≤ 0.2 .

Method 2: The planned sample size for the Japanese group in a MRCT was to satisfy:

$$P(D_1 > 0, D_2 > 0, \dots, D_s > 0) > 1 - \beta' \quad (4)$$

where D_i represents the observed treatment effect for region i , $i = 1, \dots, s$. Here, the s is to denote the number of regions.

Consistency Requirement for Regional Approval

Based on the Japanese MHLW guidance, a couple of statistical methods were proposed to apply the overall results of the MRCT to the specific region. As mentioned in the study by Chen et al.,^[29] two qualitative methods were usually considered to assess the consistency in treatment effect between each region and the entire trial. The first is to evaluate if the estimated regional treatment effect preserves some proportion of overall treatment effect, i.e., $\hat{\delta}_i > \pi_i \hat{\delta}$, which utilizes the spirit of method 1 in Japanese guidance. Here, the value of π_i should be prespecified. The second is to test if the treatment effect based on the samples from local region is statistically significant at level α_i , i.e., $\hat{\delta}_i > z_{1-\alpha_i} \sqrt{2\sigma^2/N_i}$. Tsong et al.^[30] proposed to determine

the regional type I error rate α_i adjusted for the regional sample size. Teng and Chang^[31] proposed a unified consistency requirement that generalizes the two above consistency requirements. This unified consistency requirement is to test whether the “true” regional treatment effect preserves some proportion of the “true” overall treatment effect at significance level α_i , we can use hypothesis test:

$$H_0: \delta_i \leq \pi_i \delta \text{ versus } H_a: \delta_i > \pi_i \delta \quad (5)$$

Denote Z_i as the test statistics of the hypothesis test above, where $Z_i = (\hat{\delta}_i > \pi_i \hat{\delta}) / \text{std}(\hat{\delta}_i > \pi_i \hat{\delta})$, and then $Z_i > z_{1-\alpha_i}$ is the unified consistency requirement. When $\alpha_i = 0.5$, $Z_i > z_{1-\alpha_i}$ is reduced to $\hat{\delta}_i > \pi_i \hat{\delta}$ and when $\pi_i = 0$, $Z_i > z_{1-\alpha_i}$ is reduced to $\hat{\delta}_i > z_{1-\alpha_i} \sqrt{2\sigma^2 / N_i}$, two parameters π_i and α_i are involved in this consistency requirement, which make it more commonly feasible.

The commonly used primary endpoints in oncology trials are PFS, OS, and response rate, e.g., overall response rate, complete response rate. Thus, binary and survival endpoints are major endpoints for oncology trials. Teng, Lin, and Zhang^[32] compared the different consistency requirements of each type of endpoint: continuous, binary, and survival and provided the general recommendations for each endpoint based on the practical consideration.

Binary Endpoint

Suppose $n_i^l \sim B(N_i, p_i^l)$ is the number of events from the l^{th} treatment group in region i , and $\hat{p}_i^l = \frac{n_i^l}{N_i}$ is the estimated of the event rate p_i^l , $i = 1, \dots, s$ and $l = t, c$ which represent treatment group and control group, respectively. We assume the higher event rate is, the better the result is, e.g., response rate in oncology trials. There are three major measurements of treatment effect for binary endpoint, i.e.:

1. Risk difference: $\widehat{rd}_i = \hat{p}_i^t - \hat{p}_i^c$
2. Relative risk: $\widehat{rr}_i = \hat{p}_i^t / \hat{p}_i^c$
3. Odds ratio: $\widehat{or}_i = \frac{\hat{p}_i^t(1 - \hat{p}_i^c)}{\hat{p}_i^c(1 - \hat{p}_i^t)}$

Similar to continuous endpoint, the overall treatment effect is estimated from the weighted average of regional treatment, i.e., $\hat{b} = \sum_{i=1}^s (f_i \hat{b}_i)$, where $\hat{b} = \widehat{rd}, \widehat{rr}, \widehat{or}$ and $\hat{b}_i = \widehat{rd}_i, \widehat{rr}_i, \widehat{or}_i$.

If the first type of consistency requirement is imposed for regional approval, similar to continuous endpoint, the criterion below could be considered as consistency requirement for risk difference:

$$\widehat{rd}_i > \pi_i \widehat{rd} \quad (6)$$

Two consistency requirements could be considered for relative risk, the first one is the risk reduction; the second one is based on the log scale of relative risk.

1. Risk reduction: $(\widehat{rr}_i - 1) > \pi_i (\widehat{rr} - 1)$
2. Log scale of relative risk: $\log(\widehat{rr}_i) > \pi_i \log(\widehat{rr}) \Leftrightarrow \widehat{rr}_i > \widehat{rr}^{\pi_i}$

When comparing the two consistency requirements above, it is easy to prove that the consistency requirement of risk reduction is more stringent than log scale of relative risk with the same value of π_i between 0 and 1 when the overall result is positive, i.e., $\widehat{rr} > 1$. Thus, using the log scale of relative risk as consistency requirement is preferred since it is more powerful to preserve the consistency of treatment between the local region and overall result. In terms of odds ratio, the consistency requirement proposed for relative risk could be applied to odds ratio directly and the property of the two consistency requirement still holds.

Time-to-Event Endpoint

As mentioned in the study by Quan et al.,^[33] the proportional hazards model below is usually considered for survival endpoint.

$$\lambda_i(t) = \lambda_0(t)e^{\gamma} \quad (7)$$

where $\lambda_i(t)$ and $\lambda_0(t)$ are the hazard functions for treatment and control group, respectively; e^{γ} is the HR between treatment and control group. The distribution of regional treatment effect $\hat{\gamma}_i$ for balanced two-group design is asymptotic:

$$\hat{\gamma}_i \sim N\left(\gamma_i, \frac{4}{E_i}\right) \quad (8)$$

where E_i is the total number of events in region i . Assuming that the overall treatment effect for the entire MRCT is the weighted combination of regional treatment effect and the event proportion is considered as weight for survival endpoint, the overall treatment effect is $\hat{\gamma} = \sum_{i=1}^s \left(\frac{E_i}{E}\right) \hat{\gamma}_i$. The distribution of the overall treatment effect is asymptotic:

$$\hat{\gamma} \sim N\left(\sum_{i=1}^s \frac{E_i}{E} \gamma_i, \frac{4}{E}\right) \quad (9)$$

Two consistency requirements could be considered for survival endpoint, the first one is hazard reduction; the second one is based on the log scale of HR.

1. Hazard reduction: $(1 - e^{\hat{\gamma}_i}) > \pi_i (1 - e^{\hat{\gamma}}) \Leftrightarrow (1 - \widehat{HR}_i) > \pi_i (1 - \widehat{HR})$
2. Log scale of HR: $\hat{\gamma}_i < \pi_i \hat{\gamma} \Leftrightarrow \widehat{HR}_i < \widehat{HR}^{\pi_i}$

When comparing the two consistency requirements above, it can be proven that the consistency requirement of log scale of HR is more stringent than hazard reduction with the same value of π_i between 0 and 1 when the overall result is positive, i.e., $\widehat{HR} < 1$.

One or more than one consistency requirements are available for the three measurements of binary endpoint and survival endpoint. We summarize the consistency requirement for different endpoints in Table 1 and also indicate which consistency requirement is preferable in general for each endpoint/measurement. One should have better chance to demonstrate the consistency in treatment effect by imposing the recommended consistency requirement when the true underlying treatment effects are in fact consistent between the local region and overall population.

Most of the proposed consistency requirements utilize the spirit of method 1. However, Ikeda and Bretz^[34] point out an issue with the consistency requirement defined by method 1 as illustrated in the left-hand side of Fig. 7. Shaded area represents a consistent treatment effect for the region ($\hat{\delta}_i > \pi_i \hat{\delta}$) and a significant overall treatment ($\hat{\delta} > \delta_i$). However, area A has a larger overall treatment effect and a larger regional treatment effect compared to area B, but it fails to meet the consistency defined by method 1, i.e., $\hat{\delta}_i > \pi_i \hat{\delta}$. Thus, it is not reasonable to approve a drug in area B but reject a drug in area A.

Hu^[35] also mentioned that a drug should be approved in the region if the regional treatment effect in the sub-population is so large that it is significant at the normal level of one-sided 0.025 regardless of whether the overall treatment effect is significant. Therefore Hu^[35] proposed a new regional requirement which is to satisfy any one of the following three conditions:

1. Significant overall effect $\hat{\delta} > \delta_i$ and consistent regional effect $\hat{\delta}_i > \pi_i \hat{\delta}$
2. Significant overall effect $\hat{\delta} > \delta_i$ and regional effect above a certain threshold $\hat{\delta}_i > \delta_{i1}$
3. Significant regional effect $\hat{\delta}_i$ at the normal level of one-sided 0.025.

Table 1 Summary of consistency requirement for different endpoint

Endpoint	Regional requirement	Preferred in general
Continues:	Preserve π_i proportion of overall efficacy: $D_i > \pi_i D$ Regional significance at α_i : $D_i / \text{std}(D_i) > z_{1-\alpha_i}$ Unified consistency requirement: $(D_i - \pi_i D) / \text{std}(D_i - \pi_i D) > z_{1-\alpha_i}$	Yes
Binary: Risk difference	Preserve π_i proportion of overall efficacy: $rd_i > \pi_i rd$	Yes
Binary: Relative risk	Risk reduction: $(rr_i - 1) > \pi_i (rr - 1)$ Log scale of relative risk: $\log(rr_i) > \pi_i \log(rr)$	Yes
Binary: Odds ratio	Similar to relative risk	
Survival:	Hazard reduction: $(1 - e^{\hat{\gamma}_i}) > \pi_i (1 - e^{\hat{\gamma}})$ Log scale of HR: $\hat{\gamma}_i < \pi_i \hat{\gamma}$	Yes

Shaded area in right-hand side of Fig. 7 represents the reasonable approval area based on Hu's^[35] proposal.

Optimal Design for MRCT

In an MRCT, overall power is the probability of success for entire trial under the alternative hypothesis. In terms of regional success, the concept of assurance probability is usually used to measure the probability of regional approval when consistency requirement is imposed to a local region. If we consider $Z_i > z_{1-\alpha_i}$ as regional

Fig. 7 $\hat{\delta}_i$ and $\hat{\delta}$ are the estimated treatment effect and the overall treatment effect, respectively; δ_{i2} and δ_i are the statistical significant thresholds (at one-sided 0.025 level) for the regional effect and overall treatment effect, respectively; δ_{i1} is the threshold of a positive trend for the regional effect

consistency requirement, the assurance probability of region i is defined as follows:

$$AP_i = P_{\mu} (Z_i > z_{1-\alpha_i} | Z)_{z_{1-\alpha}} \quad (10)$$

The optimal goal of an MRCT is to demonstrate the treatment efficacy in all regions of interest simultaneously with adequate power when the global treatment efficacy is already proven. Thus, in order to achieve this optimal goal, the total sample size increase is sometimes ineluctable. However, different sample size allocations will lead to different total sample size increases. The optimal designs for an MRCT require appropriate allocation of the total samples to each region so that we can ensure certain overall power and assurance probabilities for all regions of interest with as smaller sample size as we can.

Two optimal designs for MRCT were proposed by Teng and Chang:^[31] 1) Minimal total sample size (MTSS) design and 2) Maximal utility (MU) design.

MTSS Design

The MTSS design is to find the minimal sample size required and the corresponding proportion for each region to ensure both desired overall power and assurance probabilities for all regions of interest, i.e.:

$$\text{Minimize: } N(\text{with the corresponding } f_i, i = 1, \dots, s) \quad (11)$$

Subject to:

$$\text{Power} \geq 1 - \beta \quad (12)$$

$$AP_i \geq 1 - \beta_i, i = 1, \dots, j \quad (13)$$

where $1 - \beta$ is the desired overall power; $1 - \beta_i$ is the desired assurance probability for region i ; $j(\leq s)$ is the number of regions of interest.

There is no constraint on total sample size for the MTSS design. However, in practice, the determination of total sample size may highly depend on the budget for the study; therefore, even though we can calculate the MTSS with the corresponding sample size proportion for each region to achieve all design requirements, the MTSS may end up to be huge, making it unfeasible for sponsors to implement. The MU design introduced below could be used with fixed/limited sample size.

MU Design

The goal of the MU design is to find the optimal sample size allocation that can maximize the global utility of the regions of interest on the premise of guaranteeing the desired overall power with the fixed total sample size, i.e.:

$$\text{Maximize: } U = \sum_{i=1}^j M_i AP_i \times (\text{with the corresponding } f_i, i = 1, \dots, s) \quad (14)$$

Subject to:

$$\text{Power} \geq 1 - \beta \quad (15)$$

$$N = N_0 \quad (16)$$

where $1 - \beta$ is the desired overall power and N_0 is the fixed total sample size that could be the maximal sample size the sponsor can afford. Here, M_i is the utility weight for region i which could be related to the number of patients or commercial viability of this region, and $\sum_{i=1}^j M_i = 1$, $j \leq s$ is the number of regions of interest.

Under the fixed total sample size, the overall power is not a good criterion to assess the performance of different sample size allocations for MRCT. As the chosen sample size allocation that can maximize the overall power may adversely affect the ability to obtain regional approval for some regions of interest, the proposed MU design by Teng and Chang^[31] is to maximize the global benefits of the drug by considering regional approval.

Adaptive Design for MRCT

The adaptive design for MRCT is more complex than that of the conventional adaptive clinical trial. During the interim analysis, we not only need to reestimate the total sample size to guarantee the overall power but also need to determine the new sample size allocation of the next stage to ensure a certain level of regional success based on the observed data. For the conventional adaptive design, the interim decision is only determined by one observed effect size; but for adaptive MRCT, we need to incorporate the observed effect size of each region in an MRCT to make decisions for both entire MRCT study and each individual region. In general, three options are available for the conventional adaptive design at interim: stop for efficacy if the observed effect size is in favorable zone; continue to the next stage if the observed effect size is in promising zone; stop for futility if the observed effect size is in unfavorable zone. In terms of the adaptive design for MRCT, the three options are applicable to both entire MRCT study and each individual region. Thus, we not only need to determine whether to stop the entire MRCT or continue to the next stage, but we also need to make the decision for each individual region whether we can stop either for efficacy or futility or continue to the next stage. Teng and Chang^[36] proposed a region-level adaptive design for MRCT including 3 steps as follows. The flow chart of this adaptive design is illustrated in Fig. 8. The study by Teng and Chang^[36] is referred for more details with regard to the statistical framework of the proposed adaptive design including the definition and the calculation of conditional power, conditional assurance probability, conditional success rate, and how to control type I error appropriately.

Fig. 8 The flow chart of the region-level adaptive design

Step 1: Initial sample size planning

The two optimal sample size allocation designs proposed in the previous section could be used for the initial sample size planning.

Step 2: Decision-making and sample size adaptation at interim

Scenario 1: If the test statistic at stage 1 is rejected at the significance level of this stage and all regions satisfy the prespecified consistency requirement, then the entire MRCT by claiming regional efficacy for all regions is stopped.

Scenario 2: If the test statistic at stage 1 is rejected at the significance level of this stage and some regions satisfy the consistency requirement, then these regions for efficacy are stopped. For the other regions in which the consistency requirement is not satisfied, for each region, either to stop at stage 1 without pursuing a claim in this region or to enroll more patients to ensure that this region satisfies the consistency requirement at next stage is decided.

Scenario 3: If the entire MRCT shows little efficacy at interim, then the entire MRCT for futility is stopped. It is not necessary to test the consistency requirements for each region in this case.

Scenario 4: If the overall result is in the promising zone, then whether it is necessary to continue to the next stage for each region based on conditional success rate is evaluated. If the conditional success rate is smaller than a given threshold, then this region will be dropped at stage

1 and the sample size planning for stage 2 will not involve this region anymore. Second, SSR and reallocation will be performed to determine the total sample size and the corresponding sample size proportions for the remaining regions to achieve both the desired conditional power and desired conditional assurance probabilities.

Step 3: Final decision

At the end of MRCT, claim the regional efficacy each as long as the overall result is significant, and the consistency in treatment effect between this region and the overall efficacy is also proven.

CONCLUSION

In order to streamline and expedite the drug development for oncology and more efficiently identify the right population with right regimen for the patients around the world, innovated study designs should be implemented for drug developments including oncology trials. We believe that adaptive design, biomarker utilization, and MRCT are three integral parts of a clinical development strategy for oncology drug.

Adaptive designs improve the chance and shorten the time that a safe and effective drug actually reaches the patient. They can also terminate an ineffective drug earlier—either in the whole, a specific patient population, or at a certain dose. Increasingly, drug makers are

interested in using adaptive design trials to accelerate clinical development and speed new medicines to patients in need. Clinical trials using a biomarker strategy may result in smaller study sizes, higher probability of trial success with the right target patient population which in turn reduces development risk and generates higher return on investment. MRCT is a more efficient strategy to expedite global clinical development and facilitate drug registration globally compared to bridging study and multiple regional clinical trials. The ultimate goal of MRCT is to bring new drug to patients globally as fast as possible and reduce the drug lag. MRCT also helps in expansion of clinical research into developing countries bringing medical care options to subjects who otherwise may not have access to them.

Finally, careful planning, regulatory agreements, and practical implementation of these innovative designs are the key to make the speedy and successful drug development a reality.

Onset of Action

Thomas R. Stiger and Christy Chuang-Stein

Pfizer Global Research and Development, Groton, Connecticut, U.S.A.

Abstract

In this entry, we discuss four approaches that have been used to assess onset of action. These four approaches address the onset question very differently. Some tackle the question directly with the help of a definition of onset at the individual level; others compare treatment effect at specific time points.

Keywords: Fast acting; Time to response; Survival analysis; Dynamic response; Mixture models.

INTRODUCTION

Fast onset of beneficial effect is often a very desirable attribute for a pharmacological agent. The time frame that would constitute fast onset depends on the disorder and the expectation of an effective therapy for the disorder. For analgesics, for example, fast onset of pain relief is gauged in terms of minutes after administration of drug, whereas for most psychiatric disorders, time to substantial improvement for nearly all therapies takes much longer and requires multiple dosing over several days. Although many psychiatric disorders—such as depression—are chronic in nature, these conditions are often associated with acute exacerbations in which there are significant impairment and possible life-threatening (e.g., suicide) behavior. This impairment to social and occupational functioning can be great, resulting in disruption to family and social networks, as well as lost productivity. Costly treatment interventions, such as admission to an acute psychiatric ward for stabilization, are often required to ensure the safety of the patient or of those around him. The latter contributes to the economic burden of the syndrome. As a result, pharmacological interventions that could lead to rapid relief of the most distressing symptoms, or shorten the time to response or remission of the overall syndrome, could bring great value to the management of patients afflicted with these disorders. This is especially so in a resource-constrained environment.

In this entry, we discuss four approaches that have been used to assess onset of action. These four approaches address the onset question very differently. Some tackle the question directly with the help of a definition of onset at the individual level; others compare treatment effect at specific time points. While not dismissing any approach as inappropriate, we point out what type of questions these approaches can and can't answer, along with their advantages and disadvantages. To facilitate comparisons

of approaches, we provide a high-level summary of these approaches side by side in [Table 1](#).

STATISTICAL CONSIDERATIONS AND APPROACHES

Leon^[1] argued that four critical questions must be addressed in any valid analysis of comparative onset of therapeutic effect among antidepressant drugs. They are (1) how is onset defined, (2) how is onset measured, (3) how the treatment groups can be compared statistically with regard to onset of effect, and (4) how these issues affect protocol designs. Even though Leon discussed the above questions in the context of antidepressants, these four questions are often equally applicable when comparing onset of action among treatments for many other disorders.

In our discussion, we use the terms “response” and “action” interchangeably, even though “response” is used to describe the experience of a subject, while “action” is used to describe the effect of an intervention (e.g., treatment). Because a treatment's action is ultimately established through the patient's response to the treatment, we feel comfortable treating these two terms interchangeably without making an effort to distinguish between them. On those occasions when we use “onset of action” to represent the point when the treatment begins to have a clinically perceptible benefit, and “response” to represent a clear and meaningful improvement, we will explicitly state that in the text. In the latter case, a response, if confirmed, occurs after the onset of action.

Analysis at a Prespecified Early Time Point

In many clinical trials, repeated measurements of the primary endpoints are collected at earlier times despite the fact that the primary analysis is a landmark analysis at a

Table 1 A High-Level Summary of Four Approaches As well As Their Advantages and Disadvantages for Analyzing Onset of Action

Approach	When to Use	Advantages	Disadvantages
Approach #1: Analysis at a prespecified early time point	When one is interested in a different treatment effect at specific time points	It is simple	Does not define onset and does not address the distribution of onset directly
	A single time point is defined and accepted as being early	It is applicable to both a continuous and categorical endpoint (e.g., responder status)	Requires defining what time point is early and of interest
	Multiple time points are specified	It is capable of addressing sustained response in a responder-like analysis	Need to adjust for multiplicity if there are multiple “early times” unless one is willing to test sequentially When sustainability for a continuous outcome is defined by statistical significance at all subsequent time points, this procedure will suffer from a reduced power The approach is not robust to missing data unless missing can be assumed to occur completely at random
Approach #2: Repeated measures models	When one is interested in a different treatment effect at specific time points	Can handle continuous and categorical endpoints	Does not define onset and does not address the distribution of onset directly
	A single time point is defined and accepted as being early	Uses all the available data	Requires defining what time point is early and of interest
	Multiple time points are specified	Is robust to missing data as long as one can assume “missing at random”	Hard to interpret when treatment effect changes from positive to negative over visits
	It is desirable to see how the comparative treatment effect might vary over time	Sensitive for detecting nonparallel profiles	Using a slope to describe treatment effect might over-simplify the effect profile
	When one is interested in the rate of improvement and equates a higher rate with an earlier onset		Can’t address the missing data situation when using this approach for sustained response based on a binary outcome
Approach #3: Survival analysis	Onset of action could be clearly defined and time to onset can be ascertained for each subject even if it is only known to occur within an interval determined by the study	One can estimate the distribution of the onset time for each treatment	Requires a definition for “onset of action”
	When testing whether one treatment has a faster onset than another	At the population level, one can compare the onset distributions and demonstrate that time to onset is shorter in one treatment compared to another	Dichotomizing a continuous variable may be arbitrary and will result in a loss of sensitivity
		Makes use of all data up to the point of dropout for individuals who drop out	Assumption of independence of censoring and response may be questionable, especially if “sustainability” is required Inference is sensitive to combined effect of time to onset and proportion reaching onset

(Continued)

Table 1 A High-Level Summary of Four Approaches As well As Their Advantages and Disadvantages for Analyzing Onset of Action (Continued)

Approach	When to Use	Advantages	Disadvantages
Approach #4: Survival analysis using mixture models	Onset of action could be clearly defined and time to onset can be ascertained for each subject even if it is only known to occur within an interval determined by the study	Can simultaneously estimate the probability of ever reaching onset and time to onset among those reaching onset	Requires a definition for “onset of action”
	When testing whether one treatment has a faster onset than the other between two comparably efficacious treatments (in terms of overall response)	Allows one to make inferences on both questions of interest	Dichotomizing a continuous variable may be arbitrary and will result in a loss of sensitivity
	A substantial number of subjects will never experience onset if they haven’t reached onset by trial end	Makes use of all data up to the point of dropout for individuals who drop out	Assumption of independence of censoring and response may be questionable, especially if “sustainability” is required
		Considerably more sensitive than ordinary survival analysis when there is a comparable yet non-trivial proportion of non-responders	Trial may not be long enough to definitively rule out future response for those who did not respond before the end of the trial

chosen time point at or near the end of the treatment period. It is not unusual for these repeated measurements to be taken at closer intervals earlier in the trials. When a time point signaling early onset can be defined, one can compare treatment groups at the prespecified time point. A statistically significant difference between treatment groups at the early time point suggests differential treatment effect as early as the time point identified.

If the outcome variable of interest is continuous or nearly so (e.g., an ordinal scale with at least five categories), a simple linear model [e.g., one- or two-way analysis of variance (ANOVA) or analysis of covariance (ANCOVA)] can be used to compare treatment means at the specific time point. These linear models are efficient and robust to moderate deviations from the usual assumptions of normality and homogeneity of variance (i.e., maintains the Type I error rate at or below the specified level). If the outcome variable of interest is dichotomous (e.g., response or no response, event or no event), one can compare the proportion of responders between treatments via a chi-square type of test or by logistic regression. The latter allows for the adjustment with covariates considered to be associated with the response variable.

There is an increasing trend to conduct a responder analysis under which a dichotomous variable is created from a continuous one, using a cutoff value to define a response. Although dichotomization often decreases our ability

to detect a difference in the treatment effect because of the loss of information,^[2] the practice of defining a target value for treatment benefit at the individual patient level has made the responder analysis a popular one from the clinical perspective in recent years.^[3]

When a significant difference is identified at an early time point specified a priori, it is often felt that the difference needs to be sustained (at subsequent time points) to be clinically meaningful and to reduce the chance of a spurious finding. Although this requirement seems reasonable from the clinical perspective, it creates a statistical multiplicity problem in that the probability of reaching statistical significance at all subsequent time points could be substantially less than that at a single time point. This is especially so if the correlations among the test statistics at different time points are low. Besides, the analysis at each subsequent time point will be affected by dropouts and how dropouts are handled. As a result, one needs to address these issues when employing this approach.

When the primary endpoint is binary, another option is to compare the proportion of subjects who achieved a responder status at the early time point and remained so for the remainder of the study. A less stringent criterion might be to look at the proportion of individuals who achieved “onset”—for example, a 30% improvement (from baseline) at the early time point and maintained this improvement throughout the study, even though a true response required

a 50% reduction. The choice of the percentage improvement in this case might be based on what constitutes a minimal clinically meaningful improvement.

One prerequisite of the time-point analysis is our ability to define in advance the early time point of interest. If multiple time points are specified with the hope that one of them will represent the beginning of a differential treatment effect, adjustments for multiple comparisons need to be considered if the objective is to claim, via hypothesis testing, differential treatment effects for at least one of the chosen early time points. Alternatively, if one begins by testing at the latest time point and proceeds to the earlier time points backward only if statistical significance is declared for the former, one can conduct each comparison at the desirable level (e.g., 5%, as this is a special case of a step-down approach). Implicit in this approach is the assumption that one is interested in sustained response.

It should be pointed out that a statistically significant difference at an early time point implies that the drug has a different effect at that time point from the comparator (e.g., the placebo). Because *p*-values are highly affected by sample sizes, one should follow a statistically significant difference by examining the clinical relevance of the observed difference. Comparing mean changes at prespecified time points does not necessarily provide information on the actual time of onset of action at the individual level. For this reason, findings from this approach are typically interpreted at the population level.

Repeated Measures Analysis

Repeated measures analysis includes all observed data in a single model. A popular one is a likelihood-based, mixed-effects repeated measures model.^[4] The fixed effects typically include terms such as treatment, investigator, time (visit), treatment by time interaction, baseline response, and possibly baseline by time interaction. Under this model, comparisons at specific time points can be conducted using contrasts in treatment group means. One special feature of this model is the inclusion of a treatment by time interaction term. This interaction term, when significant, suggests that the mean response profiles for the treatment groups are not parallel over time. This plus point estimates of the treatment group means at each time point can be used as evidence for differential treatment effect at specific time points.

The repeated measures models have a within-subject variance component that is usually smaller than the between-subject variance component. The former can be used to test the time by treatment interaction, resulting in a more sensitive test for the interaction. The likelihood-based, mixed-effects repeated measures model is an effective and robust method for dealing with dropouts and missing data when the mechanism for missingness is dependent only on the observed values (i.e., not dependent on the values of the missing measurements).^[5] Repeated

measures analysis may also be more appropriate relative to other methods (e.g., survival analysis) when assessment visits are unevenly spaced and far apart in time.

The repeated measures model is simplified considerably when time is considered as a quantitative variable and the treatment by time interaction is reduced to fitting a separate slope parameter for each treatment group over time, suggesting a linearly monotonic response over time within each treatment group (i.e., a separate linear regression line is fitted for each treatment group). Because response to treatment often plateaus after a period of time, the model containing a slope parameter for each treatment group would be the most sensible when all the time points included in the analysis are during the period when the response continues to change approximately in a linear fashion.^[1] The latter is not an issue if there is only one post-baseline evaluation. When fitting a separate slope to each treatment group is appropriate, one can infer that the rate of change differs between treatment groups starting early on, suggesting that the group with a steeper rate of change has an earlier onset of action.

The concept of repeated measures models is also applicable to categorical data. Leon^[1] and Brannan et al.^[6] used a categorical repeated measures model to assess the probability of onset at each visit, with onset defined as achieving a certain degree of improvement from the baseline. These authors have also used the repeated measures models to look at the probability of being in a sustained improvement state at each visit. Because sustained improvement requires a subject to stay in the study for the entire treatment duration, repeated measures analysis that incorporates the sustained improvement requirement mitigates the utility that the usual repeated measures model has for handling missing data.

Similar to the analysis at a prespecified early time point, repeated measures analysis does not address the question of onset of action directly. The latter is a drawback of all analyses that test for differences in the mean changes without comparing the change amount with that required to qualify as an “action” on the part of the treatment. This drawback is rectified by the approaches included in the next two sections.

Survival Analysis

Survival analysis is by far the most commonly used analysis to address the onset of action. To use this analysis, one needs to define what qualifies as an “action” of the treatment or a “response” on the patient receiving the treatment. When a definition is given, we can look at the time required to achieve the response. Each individual has a time measurement that corresponds to the actual onset of response if he or she achieved a response, or the last assessment time if he/she failed to achieve a response. In the latter case, the onset of action is said to be censored. Because the onset time can vary among individuals, the distribution

of the onset time among a group of subjects becomes the point of interest in this analysis. Survival analysis is commonly used and is still appropriate when the actual onset of response is not known precisely, such as when measurements are taken only at prespecified time intervals. This analysis can benefit, however, from multiple measurements obtained at reasonably selected time intervals.

The Kaplan–Meier (K–M) Product-Limit method^[7] is the chosen method for estimating the distribution of the time to onset. This distribution is usually denoted as $S(t)$ and is referred to as the survival function: $S(t) = \text{Prob}\{T > t\}$. More explicitly, $S(t)$ is the probability that the time-to-onset random variable T for any individual given a certain treatment is greater than some constant real number t . For individuals who dropped out of the study, this method includes information from such individuals until the point of dropout. Using the K–M method, one can estimate $S(t)$ or, equivalently, the proportion of subjects in each treatment that will have achieved onset by any time t . In Fig. 1, for example, the K–M curve for treatment “A” indicates that it is estimated that 30% of the subjects treated with “A” will experience onset of action by Day 10. It also shows that Day 29 is the estimate in which 50% of the patients treated with “A” will have experienced onset of action. If a greater than $z\%$ response rate by time t qualifies for an early onset of action at the population level, the survival analysis could be used to decide whether the criterion is met.

When applying the K–M approach, one typically looks at the time when a subject achieved his/her first response without requiring such response to be sustaining. There are situations when sustaining response is required to qualify for a treatment action. In such a case, time to onset could be defined as the time to the first response among those with a sustained response and will be censored at the last observation time point for those who did not. There are also situations in which the onset could be defined by a lesser improvement as long as the required improvement was obtained later in the trial. For example, it is

Fig. 1 K–M estimates of $S(t)$ for two treatments

not unusual to require a 50% reduction in the Hamilton Depression (HAM-D) score (from baseline) to qualify as a responder in a depression trial. However, one can define the first time a 30% improvement is realized as the onset of action for those who eventually obtained a 50% reduction in the HAM-D score. Brannan et al.^[6] focused their time-to-onset analysis on a 30% sustained improvement in a depression trial of duloxetine using the survival type of analysis.

The approach of using different thresholds for the initial and the eventual improvement described above is similar to the stopwatch approach typically used in assessing the onset of action of analgesics in treating acute pain. For individuals who eventually received meaningful pain relief, the first time they experienced a noticeable decrease in pain (as registered using a stopwatch) is used as the time of onset for the analgesic under testing at the individual level.

To compare two treatment groups with respect to their distribution of onset of action under the survival analysis, two nonparametric tests (i.e., logrank and Wilcoxon test) are often used. Between these two, the Wilcoxon test is more sensitive to differences occurring earlier along the time scale, whereas the logrank test is more sensitive to later differences. To take into account important covariates that are thought to be associated with the onset time, semiparametric methods (e.g., Cox’s proportional hazards model) and parametric models (e.g., the Weibull distribution) can be used for both estimation and inference.

When p -values from the above comparisons are significant, one can conclude that one treatment has a faster onset than the other. This information alone does not convey information on important characteristics of the distribution of onset of action. Using the estimated time-to-onset curve, however, one can estimate the percent of individuals who have achieved onset of action by a given time. Conversely, one can estimate the time by which a given percentage of patients will have achieved onset of action. One can estimate, for example, the time by which at least 50% of the patients will have achieved onset of action if the curve has crossed the 50% mark. Depending on the disorder, this estimated curve might qualify the treatment as one with an early onset of action for the underlying disorder.

When comparing the onset of action between treatment groups, a concern with a less frequent assessment schedule is that one might miss a small but meaningful improvement in onset of action for a new drug due to heavier interval censoring. Intuitively, more frequent assessments could increase the power of a trial to detect early onset if a drug in fact has the ability to produce a more rapid response than its comparator early on. The potential increase in power from utilizing a daily assessment schedule instead of a weekly schedule was evaluated in a simulation study by Tamura et al.^[8] using distributions that fit historical time-to-response data based on the HAM-D. Tamura et al. reported only an incremental increase in power when assessments were

conducted daily instead of weekly. Because of the small increase in power, Tamura et al. questioned whether the small increase was worth the added cost and complexity of daily assessments.

Survival Analysis Using Mixture Models

Assuming comparable dropout patterns in different treatment groups, comparing the distributions of time to onset between groups using the survival analysis described above is influenced by two factors: the difference in onset rates and the difference in time to onset among those who will experience onset. When two treatment groups have comparable onset rates and similar dropout patterns, comparing time to onset using the survival analysis is similar to comparing time to onset among those who will experience onset. On the other hand, when a significant difference in the onset distributions is concluded, this difference could be due to a difference in onset rates, a difference in the time to onset among those who will achieve onset, or a combination of both. In other words, the survival approach, when applied to all subjects in the group, does not address the question of time to onset exclusively. For this reason, the method in this subsection is the most appropriate for comparing a new treatment with an active control when the two treatments are expected to produce a high percentage (but not 100%) of patients who experience onset of action.

The usual application of survival analysis treats nonresponders as censored at the last assessment time point and assumes that the nonresponders would eventually have responded had the trial or follow-up period been longer. Further, the usual analysis assumes that nonresponders are in the tail portion (which is beyond the end of the trial) of the same time-to-response distribution as the responders. Such assumptions are often inappropriate when analyzing clinical trials of central nervous system (CNS) disorders, because some individuals will never respond to a treatment no matter how long they receive it. Taking depression as an example, it is generally believed that if a subject hasn't experienced a response by Week 6 or Week 8, he or she is not likely ever to experience the desirable treatment effect even if the treatment were continued beyond Week 8 (Tamura et al.).^[8]

Because of the above considerations, some researchers have felt that one ought to consider two properties when characterizing the efficacy of a treatment in many therapeutic areas. The two properties involve the proportion who will respond and the time to response conditional on achieving a response. Or if the interest is in onset instead of a more complete response, the two properties are the proportion of subjects who experience onset and the time to onset conditional on achieving onset. Because the population of interest consists of a mixture of responders and nonresponders, models that address these two-in-one analyses are often called mixture models.

In terms of nonparametric approaches, Laska and Siegel^[9] outline how one can use K-M estimators to estimate the proportion of responders (p) and the distribution of time to response conditional on achieving a response, denoted as $S^*(t)$. The K-M estimates of $S^*(t)$ is based on the following relationship: $S^*(t) = [S(t) - (1-p)]/p$. Fig. 2 is a plot of the two estimated $S^*(t)$ s (one for each treatment) vs t using the estimated $S(t)$ s contained in Fig. 1, where $1-p$ for each treatment is estimated by the estimated $S(t)$ s at Day 42. If one assumes or concludes that the proportions of responders for the two treatments are equal, one can use the logrank or Wilcoxon test for comparing the conditional time-to-response distributions. Unfortunately, neither test is very powerful—especially the logrank test when there is a substantial proportion of nonresponders. Orazem^[10] has proposed a weighted logrank test that is more powerful in the mixture setting. This test was constructed to have maximum sensitivity when the conditional hazards are proportional. When the nonresponse rate is 40%, for example, this test may have as much as 90% power when the logrank test has a power of only 20%.^[11]

When the proportions of responders are not the same, a generalized logrank test has been proposed.^[10] Its derivation, however, assumes no ties in the onset times, and its distributional assumptions are suspect for sample sizes smaller than 100 per group. A Cramer-von Mises statistic has been proposed^[8] for comparing two conditional time-to-response distributions regardless of whether the response proportions are the same between the treatment groups. The power of this method is comparable to Orazem's logrank test^[11] when there are proportional conditional hazards, and is likely to be superior under other circumstances. The methodology is computationally intensive because it relies on bootstrapping methods.

One can use a parametric approach to combine two models.^[12] One model estimates the probability of achieving a response, often done through logistic regression. The second model describes the distribution of time to response conditional on experiencing a response. The choice of

Fig. 2 K-M type estimates of $S^*(t)$ for two treatments

distribution depends on how well the characteristics of various distributions fit the data. Two common choices are the Weibull and the log-logistic, both of which are accelerated “failure” time models. The latter means that the onset time for one treatment is a multiple of the onset time of another. The Weibull model imparts the assumption of proportional hazards, whereas the log-logistic imparts the assumption of proportional odds. These various assumptions may not be tenable, but they can be checked to some degree using the data. When the assumptions are reasonable and the models are appropriate, the parameters often provide clinically useful interpretations. To test whether the conditional time-to-onset distribution is less in one treatment compared with another, one can use likelihood ratio tests. These models can also accommodate important covariates considered to be associated with the response.

Semiparametric mixture models that are an extension of the Cox proportional hazards model have been proposed and evaluated (Peng and Dear;^[13] Sy and Taylor^[14]). Although these models appear to have some nice properties with fewer distributional assumptions, the power of such models for testing the equality of the conditional time-to-onset distributions is often inferior to that of parametric approaches.

CONCLUSIONS

In this entry, we reviewed several popular statistical and methodological approaches to analyzing onset of action. In general, approaches that look only at the first occurrence of a response without addressing subsequent responses do not take into account the dynamic nature of a patient’s response over time. If the latter is important, one should consider using the repeated measures approach or applying survival analysis to the onset of a sustained response. Whether the ensuing analysis leads to a conclusion of an early onset of action depends on the definition of early onset, as well as on the therapeutic efficacy expected of the medications used to treat the underlying disorders.

As demonstrated in this entry, many definitions can be used to define onset of action. The definition should be based on what makes sense clinically, considering the disorder under investigation and the mechanism of action of the treatment. When the definition of an onset of action is determined, statistical methods can be used to characterize the distribution of the onset time among a group of subjects.

Statistical approaches and methods for assessing the onset of action should be dictated by the specific objectives of the drug program, as well as by the underlying questions. If the product profile specifically mandates efficacy at Week 1, for example, a comparison with placebo at Week 1 in a randomized study generally would be warranted, with the hope of demonstrating superiority at that time point. On the other hand, if the product profile dictates a faster efficacy than a standard treatment with (ideally)

a comparable final response rate [e.g., new antidepressant vs generic selective serotonin reuptake inhibitors (SSRI)], a time-to-response methodology would be appropriate. In the latter case, a definition of a response is necessary to conduct the analysis.

In addition to the above two considerations, the choice of statistical approaches and methods for evaluating the onset of action is likely to depend on where the candidate is in the development program. If the goal is to obtain some favorable statements in the label (e.g., sustained efficacy over 8 weeks beginning at Week 1), comparisons with the comparator are likely to be based on conservative methodologies agreed upon in advance with the regulatory agencies. On the other hand, if the intent is to provide some credible evidence in support of early onset for a publication or to assist internal decisions, there should be more flexibility in choosing the analytic approaches.

With a clear onset definition and a prespecified analytical approach, one’s ability to differentiate between treatment groups with respect to the onset of action is likely to be a function of the dose, as well as a function of how the treatment is given. In a trial in which the study drug is given in an escalating fashion to minimize adverse drug reactions, for example, one can expect a slower onset. If one wants to know how early the onset of action could be if the drug is given at its fully intended dose(s) from the beginning, one should employ a fixed-dose design wherein patients are randomized to the full dose(s) under investigation.

If one is interested in drawing inference on onset for each individual dose in a confirmatory trial with multiple doses, one will need to employ a multiple comparison procedure to control the overall false-positive rate. One of the most popular multiple comparison procedures for this application probably is the gatekeeping procedure, in which we compare each dose with the comparator according to a prespecified order. If we think that onset is a monotone function of the dose, for example, we would compare the highest dose with the comparator first. If this yields a significant result, we proceed to compare the next-highest dose with the comparator. If the overall Type I error rate is set at the 5% level, each comparison will be conducted at the 5% level, and the comparisons will stop the instant we fail to conclude a significant difference. If we are not sure of the onset-dose relationship, we should consider using other multiple comparison procedures that do not depend on a priori assumption of the onset-dose relationship.

In summary, it is important that one have a clear definition of onset of action and a thorough understanding of how the onset will be measured. The appropriate analytic approach can be selected only after the definition, the data type, and the study objectives have been determined. Given the historical difficulty companies have had in demonstrating rapid onset of action, it is essential that great care be placed on study design and on the selection of the appropriate statistical methodology.

Optimal Futility Interim Design

Zhongwen Tang

Novartis, East Hanover, New Jersey, U.S.A.

Abstract

This entry covers two major paradigms for optimal futility interim design—frequentist operational characteristics based approaches and probability of success based approaches. The design paradigms are demonstrated in three different types of trials—single arm trial with a binary end point, randomized trial with a normal end point, and randomized trial with a time-to-event end point. The entry concludes with a comparison of the two-design paradigms and a discussion.

Keywords: Predictive probability of success; Conditional probability of success; Credible interval; Decision rule; Optimal design; Utility function; Bayesian design; Design paradigm.

INTRODUCTION

Now-a-days many clinical trials are designed in a sequential way. An interim analysis (IA) is planned to allow the trial to stop early. Based on the interim data, if a trial is doomed to fail, early stopping due to futility can help to save valuable resource for more meaningful things and spare patients of lesser treatment.

The U.S. Food and Drug Administration (FDA) guidance defines futility as “when the likelihood that the treatment effect being sought, based on the interim data, is very unlikely to be established.”^[1]

The treatment effect being sought depends on the safety profile of the treatment. If the treatment has a clean safety profile, establishing statistical significant efficacy may be enough for registration. However if there are safety concerns, health authorities (HA) will require the magnitude of treatment effect to be larger than statistical significance, i.e., clinically meaningful result is needed to support the registration.

How to design futility interims in an optimal way is the focus of this entry. Since 1 futility IA is commonly used, the discussion will focus on 1 IA scenario. But the paradigms can be extended to more than 1 IA situation.

Based on the design paradigms, current optimal futility interim design can be divided into two categories.

1. Frequentist operational characteristics (FOC) based approaches—optimality is achieved by maximizing/minimizing some utility function with respect to the design parameters, while maintaining the type I error rate and power at a specific treatment effect size.
2. Probability of success (POS) based approaches—optimality is achieved by satisfying some decision rules in terms of POS in an optimal way with respect to the design parameters.

3. The design paradigms are demonstrated in three different types of trials—single arm trial with a binary end point, randomized trial with a normal end point, and randomized trial with a time-to-event end point.

METHODS

FOC-Based Approaches

In Frequentist setting, the treatment effect equals a specific value. Power is the probability of observing statistical significance in the trial. In FOC design paradigm, a utility function, based on an important design dimension such as sample size, is preselected. The optimal design is found via maximizing/minimizing the utility function with respect to the design parameters while maintaining the type I error rate and the power at a specific treatment effect parameter value. This design paradigm can be dated back to several decades to the work done by Weiss^[2] and Lai.^[3] It got popular after the work done by Simon^[4] for futility IA with binary end point to minimize sample size while holding the type I and type II error rates in two stage setting (with only 1 IA). The method can be extended to many slightly different scenarios including different end points (e.g., Chen et al.,^[5] Wason and Mander^[6]), different utility functions (e.g., Chen et al.^[5]), different parameter value (e.g., Mander and Thompson^[7]), more than 1 IA (e.g., Wason et al.^[8]), allowing stopping for efficacy at IA (e.g., Manders and Thompson^[7]), etc.

The FOC design paradigm will be demonstrated in three different types of trials in the following sub sections.

Single Arm Study with Binary End Point

Consider a single arm trial of two stages with sample size n_1 and n_2 in stages 1 and 2, respectively. If the number

of responses at the first stage is r_1 or fewer, the trial is terminated due to futility.

Simon (1989) proposed to optimize the design by minimizing the expected sample size, denoted as EN, under null hypothesis response rate p_0 holding the type I error rate (α) and type II error rate (β). No stopping due to efficacy is allowed at IA.

$EN = n_1 + (1 - PET)n_2$, where PET is the probability of early termination after the first stage. PET depends on the true response rate p . $PET = B(r_1; p, n_1)$, where $B(r_1; p, n_1)$ is the cumulative probability function of a binomial distribution with response rate p , i.e., the probability of observing r_1 or fewer responses out of n_1 observations. If there are total r or fewer responses observed at the end of the trial, the trial fails. Hence the probability of failing is:

$$B(r_1; p, n_1) + \sum_{x=r_1+1}^{\min(n_1, r_2)} b(x; p, n_1)B(r - x; p, n_2) \quad (1)$$

Type I and type II error rates can be computed using this formula with p from H_0 (null hypothesis) and H_1 (alternative hypothesis), respectively.

With prespecified parameters p_0 , p_1 (response rate at H_0 and H_1) α , β , the optimal design is found by minimizing the expected sample size with respect to the design parameters—total sample size n , IA sample size n_1 , cutoff response numbers at the IA (r_1), and final analysis (r).

Simon also proposed to use the maximal sample size as the utility function. The maximal sample size refers to the sample size at the final analysis, i.e., no stopping at IA. This approach leads to the so-called min-max design.

Randomized Two-Arm Study with Normal Outcome

Consider a two-arm randomized trial with a normal end point comparing an experimental treatment and a control treatment. Assume the individual response from control treatment has normal distribution with mean μ_c and variance σ^2 , i.e., $N(\mu_c, \sigma^2)$ and from experimental treatment σ^2 , i.e., $N(\mu_e, \sigma^2)$. $\delta = \mu_e - \mu_c$ is the true difference in the treatment effect between the experimental and control treatments. Bigger δ indicates bigger treatment effect. The stagewise test statistic is a two sample t statistic, denoted as T_1 and T_2 for stages 1 and 2, respectively. T_1 and T_2 are independent of each other. The trial can be stopped due to either, efficacy or futility at IA. If $t_1 < f$, the trial-stops for futility. If $t_1 > e_1$, the trial stops for efficacy. f is the futility boundary in the t test statistic scale, e_1 is the efficacy boundary at the IA in the t -test statistic scale.

Wason and Mander^[6] proposed to find the optimal design by minimizing the expected sample size EN holding the type I and type II error rates.

$$EN = n_1 + (1 - PET)n_2 \quad (2)$$

where $PET = P(T_1 < f) + P(T_1 > e_1)$, and n_1 is the number of patients in the first stage and n_2 is the number of patients in the second stage, if the trial does not stop at IA.

T_1 has noncentral t distribution with noncentrality parameter $\frac{\sqrt{r(1-r)n_1}\delta}{\sigma}$ and degrees of freedom $2n_1 - 2$.

σ is assumed to be known or can be estimated from existing data at design stage. r is the randomization ratio = number of patients in the control arm/total number of patients in both arms.

The test statistic in the final analysis is $T = \frac{\sqrt{n_1 T_1 + n_2 T_2}}{\sqrt{n_1 + n_2}}$. The trial will declare success if $t > e_2$ in the final analysis. The probability of failing to reject H_0 is:

$$\begin{aligned} P(\text{fail to reject } H_0) &= P(T_1 < f) + P(e_1 \geq T_1 \geq f, T \leq e_2) \\ &= P(e_1 \geq T_1 \geq f, T_2 \leq \frac{\sqrt{n_1 + n_2}e_2 - \sqrt{n_1}T_1}{\sqrt{n_2}}) \\ &= \int_{-\infty}^{(\sqrt{n_1 + n_2}e_2 - \sqrt{n_1}f)/\sqrt{n_2}} \int_f^{e_1} g(t_1)h(t_2)dt_1 dt_2 \end{aligned} \quad (3)$$

where $g(t_1)$ and $h(t_2)$ are the density functions of T_1 and T_2 , respectively. Type I and type II error rates can be calculated using this formula.

Wason et al.^[8] also proposed to use the maximum expected sample size parameter with respect to the treatment effect size as the utility function. This leads to the so-called δ -min-max design.

Randomized Trial with Time to Event End Point

Consider a two-arm randomized trial with time-to-event end point comparing an experimental treatment and a control treatment. Chen et al.^[5] proposed to optimize the interim design by maximizing the following benefit/cost ratio R with respect to the futility and efficacy boundaries at IA while maintaining some operational characteristics. The trial can be stopped for either efficacy or futility at IA.

$$R = \frac{Bp(1-\beta)}{C_t + (C - C_t)[p(1-\beta_1) + (1-p)\alpha_1]} \quad (4)$$

where C_t is the cost spent at IA, C is the cost of the trial conducted until the final analysis, B is the benefit of the treatment, p is the POS (the probability of the study drug with treatment effect size at the alternative hypothesis value), assumed to be known and can be estimated from historical data, α_1 is efficacy boundary at IA in p value scale, β_1 is the type II error rate spent at IA, and β is the overall type II error rate. B is assumed to be fixed and hence does not have any impact on the design selection.

Denote Z_t as the standard normal (under null hypothesis) test statistic at the IA and Z_1 as the test statistic in the final analysis. Chen et al.^[5] proposed to find the optimal design by maximizing R while maintaining the overall power and holding efficacy boundary in p value (not POS) scale to be α_1 and α_2 , and probability of significance to be

β_1 and β_2 in IA and final analysis, respectively, which is equivalent to the following two constraints:

$$\begin{cases} P(Z_t > Z_{\beta_1} \text{ or } Z_1 > Z_{\beta_2}) = 1 - \beta \\ Z_{1-\alpha_1} + Z_{1-\beta_1} = \sqrt{t} (Z_{1-\alpha_2} + Z_{1-\beta_2}) \end{cases} \quad (5)$$

The second equation comes from the fact that the event size of a trial without IAs is inversely proportional to $(Z_{1-\alpha} + Z_{1-\beta})^2$, where α and β are the type I and II error rate, respectively.

POS Based Approaches

Efficacy boundaries based on operational characteristics do not have intuitive interpretation and hence are difficult to be communicated with non-statistician colleagues. An alternative way to design IA resorts to a statistic called POS.

This approach is based on prediction of success in the final analysis using data collected at IA. This kind of predictive approach has been used for designing sequential trials for a while. One approach is based on the so-called stochastic curtailment (Lan, Simon, and Halperin^[9] Halperin et al.,^[10] Lan and Wittes,^[11] Davis and Hardy,^[12] Dignam et al.^[13]) using the statistic called conditional power. Conditional power has been criticized for assuming that the treatment effect size equals a specific value which is not known to be true. To address this issue, conditional power is averaged with respect to the posterior distribution of the parameter to get a statistic called predictive power (Spiegelhalter and Freeman,^[14] Dignam et al.^[13]). In common practice, PP alone, is used to support decision making. As explained later, PP is a random variable. Using PP alone, without quantifying its uncertainty to support decision making can be misleading. As shown below, CP and PP are special cases of POS.

POS based optimal futility interim design was first proposed by Tang^[15] using the concept of predictive probability of success (PPOS) in a clinical trial with a time-to-event end point. This paradigm can be extended to trials with other end points.

Probability of Success

POS is closely related to CP and PP. CP is the probability of observing statistical significance in the final analysis, given the observed data and assuming the treatment effect size equals to a specific value.

$$CP = P(\hat{\theta} < \delta | \theta, F_{\text{obs}}) \quad (6)$$

where $\hat{\theta}$ is the observed treatment effect (here, smaller $\hat{\theta}$ means bigger treatment effect), δ is the statistical significance cutoff value for $\hat{\theta}$, θ is the treatment effect parameter value, and F_{obs} is the observed data.

There are two different interpretation of CP. In Frequentist setting, CP is a fixed value given that the treatment effect parameter equals to a specific value. CP in Frequentist setting is often criticized for assuming that the treatment effect parameter equals a specific value which is not known to be true. To address this issue, CP can be interpreted in the Bayesian setting. In the Bayesian setting, the treatment effect parameter is a random variable, so is CP. PP is the expected value of CP with respect to the posterior distribution of the parameter.

$$PP = \int CP f(\theta | F_{\text{obs}}) d\theta \quad (7)$$

where $f(\theta | F_{\text{obs}})$ is the posterior density of θ . It is a kind of center of CP. Summarizing CP using PP alone is not sufficient and may be misleading. Besides the center of the variable, the amount of uncertainty associated with the random variable is needed to understood completely.

Both CP and PP use statistical significance to define success. While statistical significance is required, clinical meaningfulness of the observed treatment effect may be more relevant and critical. For example, HA often require the observed treatment effect size to be bigger than statistical significance to support registration decision. To address this issue, the power concept can be extended to the concept of POS. CP can be extended to conditional probability of success (CPOS) and PP to PPOS. CPOS is the probability of observing success given the parameter equals to a specific value.

$$CPOS = P(\hat{\theta} < \delta | \theta, F_{\text{obs}}) \quad (8)$$

where $\hat{\theta}$ is the observed the treatment effect (here, smaller $\hat{\theta}$ means bigger treatment effect), δ is the success cutoff value for $\hat{\theta}$, θ is the treatment effect parameter value, and F_{obs} is the observed data.

PPOS is the expected value of CPOS with respect to the posterior distribution of the parameter.

$$PPOS = \int CPOS f(\theta | F_{\text{obs}}) d\theta \quad (9)$$

where $f(\theta | F_{\text{obs}})$ is the posterior density of θ .

The success criteria of CPOS and PPOS are not restricted to statistical significance. It can be something else such as clinically meaningful result. Note that if success is defined as statistical significance, then PPOS reduces to PP and CPOS reduces to CP. PP is a special case of PPOS, and CP is a special case of CPOS. CP is a random variable in Bayesian setting, and so is CPOS. Summarizing CPOS using its center (such as PPOS) alone is not enough. An important part is the variability associated with CPOS.

PPOS is a conditional probability conditioned on randomly observed data. When the trial is repeated, the observed data will be different. Hence the PPOS will be

different if the trial is repeated. Therefore, PPOS is also a random variable. The interpretation of PPOS is not complete without quantifying its uncertainty.

POS concepts can be used to set up decision rules with intuitive interpretation. Both PPOS and CPOS can be used for this purpose.

Decision Rule Based on PPOS

To declare futility, PPOS needs to be small and the credible interval of PPOS needs to be relatively tight.

$$\begin{cases} \text{PPOS} < c_1 \\ \text{uPPOS} < c_2 \end{cases} \quad (10)$$

where $c_1 < c_2$ and uPPOS is a high percentile of PPOS. Both c_1 and $c_2 - c_1$ are relatively small values. The first criterion mandates that the PPOS is small. The second criterion mandates the credible interval of PPOS is relatively tight. Therefore, its calculation is supported by sufficient information. Hence PPOS is not small just to chance.

Many designs satisfy the decision criteria. The optimal design, consistent with the decision rules, satisfies the following criteria. Finding the optimal design is equivalent to solving the two equations with respect to the design parameters.

$$\begin{cases} \text{PPOS} = c_1 \\ \text{uPPOS} = c_2 \end{cases} \quad (11)$$

The first equation ensures PPOS is small and so not too many trials will be prevented from entering the next stage to guard against false negative. The first equation also makes sure that the PPOS is not too small so that not too many trials will enter next stage to guard against false positive. The second equation makes sure that the PPOS calculation is supported by enough information hence, the PPOS is not small just due to chance. The second equation also ensures that the PPOS calculation does not demand too much information, and the IA can be done at relatively early to achieve the goal of saving resources.

PPOS can be computed from the predictive distribution. In Bayesian setting, the predicted distribution can be derived using the following framework if the data at IA (denoted as x) are independent of the data after IA (denoted as y), given the treatment effect parameter θ .

$$\begin{aligned} p(y|x) &= \int p(y, \theta|x) d\theta = \int p(y|\theta, x) p(\theta|x) d\theta \\ &= \int p(y|\theta) p(\theta|x) d\theta \end{aligned} \quad (12)$$

where $p(y|\theta)$ is the likelihood of future data and $p(\theta|x)$ is the posterior distribution given interim data.

Decision Rule Based on CPOS

Tang^[16] proposed to use another POS criteria to support decision making.

To declare futility, the median CPOS (mCPOS) needs to be small and the credible interval of CPOS to be relatively tight.

$$\begin{cases} \text{mCPOS} < c_1 \\ \text{uCPOS} < c_2 \end{cases} \quad (13)$$

where $c_1 < c_2$ and uCPOS is a high percentile of CPOS. Both c_1 and $c_2 - c_1$ are relatively small values. The first criteria mandate that the mCPOS is small. The second criteria mandate that the credible interval of CPOS is relatively tight. Therefore mCPOS calculation is supported by sufficient information. Hence mCPOS is not small by chance.

Many designs satisfy the decision criteria. The optimal design, consistent with the decision rules, satisfies the following criteria. Finding the optimal design is equivalent to solving the two equations with respect to the design parameters.

$$\begin{cases} \text{mCPOS} = c_1 \\ \text{uCPOS} = c_2 \end{cases} \quad (14)$$

The POS design paradigm will be demonstrated in three different trials in the following sub-sections.

Randomized Trial with Time-to-Event End Point

Consider a two-arm randomized trial with a time-to-event end point comparing the experimental treatment and the control treatment. The parameter of interest is log hazard ratio (HR) (experimental over control), denoted as θ (smaller θ means bigger treatment effect). Assume proportional hazard, i.e., θ is a constant at any time point of the survival course. The number of events at the IA is d . The total number of events in the final analysis is $d_{\max}$. Let $t = d/d_{\max}$ be the time of IA in the information scale. The time in the final analysis is 1. The test statistics is the Wald statistic based on partial likelihood from Cox regression model:

$$Z(t) = \frac{\hat{\theta}(t)}{\hat{\sigma}(\hat{\theta}(t))} \quad (15)$$

where $\hat{\theta}(t)$ is the maximum partial likelihood estimator of θ based on data at IA, $\hat{\sigma}(\hat{\theta}(t))$ is the standard error of the estimator.

$\hat{\theta}(t)$ has asymptotic normal distribution with mean equal to the true parameter and variance inversely proportional to the number of events at the IA. $\hat{\theta}(t) | \theta \sim N(\theta, \sigma_1^2 = 1/(r(1-r)d))$

where $r = \frac{\text{number of patients in control arm}}{\text{total number of patients in both arms}}$ is the randomization ratio.

POS calculation involves two components—the posterior distribution of θ and CPOS value at a specific θ value.

Posterior distribution of θ . Deriving posterior distribution of θ starts with some prior belief of the parameter. For simplicity, the prior can be assumed to be conjugate (with respect to the likelihood) normal with some mean and some variance. That is, $\theta \sim N(\theta_0, \sigma_0^2 = 1/(r(1-r)d_0))$. The variance is written in the same format as the parameter estimate variance, and hence the amount of information in the prior distribution can be quantified in terms of number of events d_0 .

The prior distribution can be updated using the interim data to obtain the posterior distribution of the parameter. The posterior distribution is also normal.

$$\theta | \hat{\theta}(t) \sim N(\phi \hat{\theta}(t) + (1-\phi)\theta_0, \sigma_0^2(1-\phi))$$

where,

$$\phi = \frac{\sigma_0^2}{\sigma_0^2 + \sigma_1^2} \quad (16)$$

The posterior mean is a weighted average of the interim estimate and the prior mean. The weights depend on the relative amount of information in the interim data and the prior distribution. The more the information from the interim data, bigger the contribution from the interim estimate. The posterior variance is a portion of the prior variance. The reduction of the variance depends on the relative amount of information in the interim data and the prior distribution. The more the information from the interim data, the bigger is the reduction. When there is no information on the prior distribution (prior number of events equals to 0), the prior information disappears from the posterior distribution. The posterior mean becomes the interim parameter estimate. The posterior variance becomes the interim parameter estimate variance.

When evaluating the final analysis at IA, the data upto the IA is fixed. The only uncertainty comes from the data between the IA and the final analysis. Using the following statistic Z^* , $Z(1)$ can be partitioned into two independent components. One component $Z(t)$ depends on the data upto IA only. The other component $\frac{\sqrt{d_{\max}}Z(1) - \sqrt{d}Z(t)}{\sqrt{d_{\max} - d}}$ is essentially the independent increment from IA to final analysis. According to Tang,^[15] Z^* and $Z(1)$ have the same distribution.

$$Z^* = \omega_1 Z(t) + \omega_2 \frac{\sqrt{d_{\max}}Z(1) - \sqrt{d}Z(t)}{\sqrt{d_{\max} - d}} \quad (17)$$

where, $\omega_1 = \sqrt{t}$, $\omega_2 = \sqrt{1-t}$.

Define success in the final analysis as $Z(1) < \delta$. This is equivalent to $Z^* < \delta$. Hence CPOS at a specific parameter value can be expressed as:

$$\text{CPOS} = P\left(\omega_1 Z(t) + \omega_2 \frac{\sqrt{d_{\max}}Z(1) - \sqrt{d}Z(t)}{\sqrt{d_{\max} - d}} < \delta \mid \theta\right) \quad (18)$$

After some rearrangements, CPOS can be expressed as:

$$\text{CPOS} = P\left(\frac{\sqrt{d_{\max}}Z(1) - \sqrt{d}Z(t)}{\sqrt{d_{\max} - d}} < \frac{\delta - \omega_1 Z(t)}{\omega_2} \mid \theta\right) \quad (19)$$

According to Tang,^[15]

$$\frac{\sqrt{d_{\max}}Z(1) - \sqrt{d}Z(t)}{\sqrt{d_{\max} - d}} \sim N\left(\theta \sqrt{r(1-r)(d_{\max} - d)}, 1\right) \quad (20)$$

hence,

$$\text{CPOS} = \Phi\left(\frac{\delta - \omega_1 Z(t)}{\omega_2} - \theta \sqrt{r(1-r)(d_{\max} - d)}\right) = f(\theta) \quad (21)$$

Bigger treatment effect (smaller θ) means bigger CPOS, hence $f(\theta)$ is a monotone decreasing function of θ . The percentiles of CPOS and θ have one-to-one relationship. $(1-\alpha)*100$ percentile of CPOS is the $f(\cdot)$ transformation of $\alpha*100$ percentile of θ . Denote $(1-\alpha)*100$ percentile of CPOS as uCPOS, then,

$$\text{uCPOS} = f\left(\text{qnorm}\left(\alpha, \phi \hat{\theta}(t) + (1-\phi)\theta_0, \sigma_0^2(1-\phi)\right)\right) \quad (22)$$

where $\text{qnorm}(p, \mu, \sigma^2)$ is the $p*100$ percentile of normal distribution with mean μ and variance σ^2 . The uCPOS $(1-\alpha)$ is the width of the $(1-\alpha)*100$ percent one-sided credible interval of CPOS.

PPOS PPOS can be analytically calculated using the predictive distribution. According to Tang, the predictive distribution is

$$\hat{\theta}(1-t) \mid \hat{\theta}(t) \sim N\left(\phi \hat{\theta}(t) + (1-\phi)\theta_0, \sigma_0^2(1-\phi) + \sigma_2^2\right) \quad (23)$$

where $\sigma_2^2 = 1/(r(1-r)(d_{\max} - d))$. The predictive distribution has the same mean as the posterior distribution and added variance due to added uncertainty of estimating the parameter using data.

Define success in the final analysis as $Z(1) < \delta$. This is equivalent to $Z^* < \delta$. Hence PPOS can be expressed as:

$$\text{PPOS} = P\left(\omega_1 Z(t) + \omega_2 \frac{\sqrt{d_{\max}}Z(1) - \sqrt{d}Z(t)}{\sqrt{d_{\max} - d}} < \delta \mid \hat{\theta}(t)\right) \quad (24)$$

Based on the predictive distribution,

$$\text{PPOS} = \Phi \left(\frac{\frac{\delta - \omega_1 z(t)}{\omega_2}}{\frac{\sqrt{r(1-r)(d_{\max} - d)} - [\varphi \hat{\theta}(t) + (1 - \varphi)\theta_0]}{\sqrt{\sigma_0^2(1 - \varphi) + \sigma_2^2}}} \right) \quad (25)$$

where $\sigma_2^2 = 1/[r(1-r)(d_{\max} - d)]$ and $\Phi(\cdot)$ denotes the cumulative density function of standard normal distribution.

$(1 - \alpha)*100$ percentile of PPOS is obtained by replacing the posterior mean $\varphi \hat{\theta}(t) + (1 - \varphi)\theta_0$ in PPOS formula by the $\alpha*100$ percentile of the posterior distribution of $\theta | \hat{\theta}(t)$. The prior information is also considered as observed data.

An example Consider a big randomized oncology phase III trial comparing the experimental treatment versus the standard care. The primary end point is progression free survival (PFS). The median PFS of the standard care is estimated to be nine months. The experimental treatment is expected to extend the median PFS for three months (corresponding to a clinically meaningful HR of 0). Patients are randomly assigned to the two arms in a 1:1 ratio ($r = 0.5$). The success is defined as observing clinically meaningful result $\text{HR} < 0.75$ after observing 500 events in the final analysis. For simplicity, a non-informative prior with zero prior events is used. When the following two conditions are satisfied, futility will be declared.

1. The predictive probability of observing a clinically meaningful HR in the final analysis is less than 20% ($\text{PPOS} < 0.2$).
2. The 80th percentile of PPOS is less than 40% ($\text{uPPOS} < 0.4$).

Finding the optimal futility interim design is equivalent to finding the solution of the following equations with respect to the design parameters—timing of the analysis t and cutoff HR at IA (HR.IA).

$$\begin{cases} \text{PPOS}(t, \text{HR.IA}) = 0.2 \\ \text{80th percentile of PPOS}(t, \text{HR.IA}) = 0.4 \end{cases} \quad (26)$$

The optimal futility interim design is to implement the IA at information fraction of $0.511 (t = 0.511, d_1 = 256)$ with a cutoff HR of 0.807.

The optimal design can be visualized using the contour plot of PPOS and uPPOS versus information fraction t and cutoff HR at IA (HR.IA) (Fig. 1). First, focus on the PPOS lines. On the top of the graph, PPOS decreases as the information increases. At the bottom of the graph, PPOS increases as the information increases. The separation is at $\text{HR.IA} = 0.75$. This is because the success is defined as a HR of 0.75. When an unfavorable HR is observed, it is more likely to be an unsuccessful trial if the PPOS calculation

Fig. 1 Contour plot of PPOS and uPPOS vs. information fraction t and cutoff hazard ratio at IA (HR.IA). The black contour lines represent PPOS. The red contour lines represent the 80th percentiles of PPOS. The success is defined as a clinically meaningful HR of 0.75 or less. The optimal design with respect to the POS decision rule is highlighted with a pair of horizontal and vertical lines crossing it

is supported by more information. If a favorable HR is observed, it is more likely to be a successful trial if the PPOS calculation is supported by more information.

The design at the intersection of PPOS 0.2 and uPPOS 0.4 line is the optimal design with respect to the POS decision rule. This can be shown using elimination method. For the designs above the PPOS = 0.2 line, the PPOS cutoff is too small, hence too many trials will enter next stage and cause too much false positive. For designs below the PPOS = 0.2 line, the PPOS cutoff is too big, hence too many trials will be prevented from entering next stage and cause too much false negative. This shows the designs above and below the PPOS = 0.2 line are inferior to the intersection design. Now the designs in the left are at the PPOS 0.2 line. For designs to the left of the intersection, PPOS credible interval is too wide and hence PPOS calculation is supported by too little information, PPOS may be small by chance. For designs to the right of the intersection, PPOS credible interval is too tight and the calculation demands too much information and it is not efficient in achieving the goal of saving resource if the treatment is doomed to fail. This shows the designs on both sides of the PPOS = 0.2 line are inferior to the intersection design. Therefore the intersection is the optimal design corresponding to the PPOS decision criteria.

Randomized Trial with Normal End Point

Consider a two-arm randomized trial with a normal end point comparing the experimental treatment and the

control treatment. The total sample size is n . The parameter of interest is treatment effect difference θ (bigger θ means bigger treatment effect). The randomization ratio is $r = \frac{\text{number of patients in the control arm}}{\text{total number of patients}}$. Assume the two treatments share a common known variance σ^2 . The sample mean difference is denoted as $\hat{\theta}$ which is normally distributed with unknown mean treatment effect θ and variance $\frac{\sigma^2}{r(1-r)n}$. Let t be the time of the IA in the information scale. The final analysis is done at time 1 in the information scale. The sample size at the IA is $n_1 = nt$. The sample size between IA and final analysis is $n_2 = n(1-t)$.

Denote the estimate at IA as $\hat{\theta}(t)$ and the estimate using the data between IA and final analysis as $\hat{\theta}(1-t)$. Denote the estimate based on all data as $\hat{\theta}(1)$.

It can be shown that $\hat{\theta}(1)$ approximately equals to $t\hat{\theta}(t) + (1-t)\hat{\theta}(1-t)$, i.e. all data estimator is an information weighted average of the stagewise estimators.

The statistics $\hat{\theta}(t)$ and $\hat{\theta}(1-t)$ are normally distributed and conditionally independent given θ , with variance $\sigma_1^2 = \frac{\sigma^2}{r(1-r)n_1}$ and $\sigma_2^2 = \frac{\sigma^2}{r(1-r)n_2}$ respectively.

For simplicity, the prior distribution of θ can be assumed to be conjugate (with respect to the likelihood) normal $N\left(\theta_0, \sigma_0^2 = \frac{\sigma^2}{r(1-r)n_0}\right)$. The prior variance is written in the same format as the parameter estimate variance, hence the prior information can be quantified in terms of the number of observations. The interim data can be used to update the prior distribution. The resulted posterior distribution is:

$$\theta | \hat{\theta}(t) \sim N\left((1-\phi)\theta_0 + \phi\hat{\theta}(t), (1-\phi)\sigma_0^2\right)$$

where,

$$\phi = \frac{\sigma_0^2}{\sigma_0^2 + \sigma_1^2} \quad (27)$$

The posterior mean is a weighted average of the prior mean and interim estimate. The weights depend on the relative amount of information between the prior distribution and the interim data. The more the information in the interim data, the bigger the contribution from the interim estimate. The posterior variance is a portion of the prior variance. The reduction of variance depends on the relative amount of information between the prior information and the interim data. The more the information from the interim data, the bigger the reduction in posterior variance.

The predictive distribution is:

$$\hat{\theta}(1-t) | \hat{\theta}(t) \sim N\left((1-\phi)\theta_0 + t\hat{\theta}(t), (1-\phi)\sigma_0^2 + \sigma_2^2\right) \quad (28)$$

It has the same mean as the posterior distribution but bigger variance due to added uncertainty for estimating parameters using data.

Define success in the final analysis as $\hat{\theta}(1) > \delta$. This is equivalent to $\hat{\theta}(1-t) > \frac{n\delta - n_1\hat{\theta}(t)}{n_2}$.

Because

$$\hat{\theta}(1-t) \sim N(\theta, \sigma_2^2), \quad (29)$$

hence,

$$\text{CPOS} = \Phi\left(\frac{\frac{n\delta - n_1\hat{\theta}(t)}{n_2} - \theta}{\sigma_2}\right)$$

Percentiles of CPOS can be obtained by replacing the θ in the equation by the corresponding percentiles of θ from its posterior distribution.

Based on the predictive distribution

$$\text{PPOS} = 1 - \Phi\left(\frac{\frac{n\delta - n_1\hat{\theta}(t)}{n_2} - (1-\phi)\theta_0 - \phi\hat{\theta}(t)}{\sqrt{(1-\phi)\sigma_0^2 + \sigma_2^2}}\right) \quad (30)$$

$(1-\alpha)*100$ percentile of PPOS, uPPOS can be obtained by replacing the mean of the predictive distribution by the $(1-\alpha)*100$ percentile of posterior distribution.

Single Arm Study with Binary End Point

Consider a single arm study with a binary end point whose response rate is p . Assume the prior distribution of P to be conjugate beta (with respect to the binomial likelihood), i.e. $P \sim \text{beta}(a, b)$. The prior mean of P is $\frac{a}{a+b}$. The amount of information is measured by the sum of $a + b$. The numbers a and b can be considered as the number of responders and nonresponders respectively out of total of $a + b$ observations.

Suppose at IA, there are n observations. The number of responders at IA is x . The posterior distribution of P is then:

$$P | X = x \sim \text{beta}(a+x, b+n-x) \quad (31)$$

The predictive distribution for the number of responders Y out of m observations in the remaining of the trial is beta binomial with the following probability mass function:

$$P(Y = y | X = x) = \binom{m}{y} \frac{B(a+x+y, b+n-x+m-y)}{B(a+x, b+n-x)}$$

where B

(x, y) is a beta function; $\binom{m}{y}$ is the m choose y function.

Define success in terms of the observed response rate in the final analysis $\frac{x+Y}{m+n} > c$. This is equivalent to $Y > (m+n)c - x$.

$$\text{CPOS}(p) = 1 - \text{pbinom}(\text{floor}((m+n)c - x), m, p) \quad (32)$$

where pbinom is the cumulative binomial density function; floor is the biggest integer no more than x .

Percentiles of CPOS can be obtained by replacing p in CPOS formula by the corresponding percentiles of P from the posterior distribution.

Based on the predictive distribution, $PPOS = P(Y > (m+n)c - x \mid X = x)$.

Percentiles of PPOS can be obtained by replacing x in the predictive distribution by the corresponding percentiles of X . The percentiles of X can be obtained by multiplying n by the corresponding percentiles of P from its posterior distribution.

CONCLUSIONS AND DISCUSSIONS

In this entry, two different paradigms for optimal futility interim design, FOC versus POS based approaches, are summarized and demonstrated in three different trial scenarios.

FOC in sequential trials does not have intuitive interpretation and hence it is difficult to communicate with non-statistician colleagues. POS have intuitive interpretation and hence can facilitate team communication and interaction with HA.

FOC based approaches need to specify a specific treatment effect size in order to calculate power. POS approaches use data driven decision without specifying a specific treatment effect size which is not known to be true.

FOC based approaches maintain power at a specific treatment effect size. Power is probability of observing statistical significance. Statistical significance is often not enough to define success. Success criteria in POS are not restricted to statistical significance. POS approaches are more useful due to its flexibility. Statistically significant, but nonclinically significant results may not translate to benefit. It may not be worthwhile saving nonclinically significant power. Evaluating POS approaches using FOC criteria may be misleading.

In FOC based methods, the futility IA is designed together with the final analysis to maintain the type I and type II error rate. In contrast, in POS based approaches, the design of the futility IA is independent of the design of the final analysis. Hence its type I error rate control is conservative. This conservativeness is desirable since futility IA is generally nonbinding to allow the flexibility to continue the trial even if the futility boundary is crossed. In FOC based methods, type I error rate control assumes a binding futility IA. This may not be practical. For example, the primary end point is a short term end point. The futility criteria for short term end point may be met at IA. But the trial may continue if substantial long term benefit is observed.

FOC based approaches achieve optimality via maximizing/minimizing some utility function. The optimality is achieved in one specific dimension defined by the utility function but may suffer in the other dimensions. In practice, it is rare to find a single dimension which is important while other dimensions are trivial and ignorable. In reality, multiple factors should be taken to consideration in trial design. One dimensional optimal design can not accommodate the complexity of the reality. In contrast,

POS based approaches can select the decision rule cutoff values by incorporating information from multiple dimensions, hence the resulted optimal design achieves the best balance among multiple design dimensions.

POS approaches involve several subjective decisions including success criteria selection, POS cutoff values selection, etc. All these decisions should be extensively discussed and well justified to minimize the potential bias. Clinical trial design team with diversified (relevant) backgrounds and smooth communication can benefit more from POS based methods.

One common issue in POS practice is using PPOS alone to support decision making. The inference about treatment effect size, say θ , depends on both the point estimate $\hat{\theta}$ and the variance of $\hat{\theta}$. PPOS and uPPOS are 1:1 transformation of $\hat{\theta}$ and the variance of $\hat{\theta}$. Hence PPOS and uPPOS are equivalent statistic to $\hat{\theta}$ and the variance of $\hat{\theta}$. Using PPOS and uPPOS for decision making is equivalent to using $\hat{\theta}$ and the variance of $\hat{\theta}$. Reducing $\hat{\theta}$ and the variance of $\hat{\theta}$ to PPOS alone will cause information loss. PPOS is a statistic calculated from data. Using PPOS alone for decision making is using a statistic for statistical inference without knowing its distribution. This doesn't make sense. By the same token, mCPOS should be used together with its credible interval to support decision making as well.

Abstract

The primary objective of this entry is to use real data sets to demonstrate the application of testing methods and provide numerical results from some of these tests.

INTRODUCTION

In clinical trials for comparing an active treatment and a standard therapy, the scale for the primary clinical endpoint is recommended to be a continuous measure in order to provide an accurate and reliable assessment. In practice, however, it is impossible, or can be extremely expensive, to measure responses continuously. Thus, in many applications, the intensity of some meaningful and well-defined event such as infection or cure of a certain disease is used as a surrogate endpoint for some unobserved latent continuous variables in clinical trials. Responses to treatments from patients are being classified into some ordered categories according to the intensity of the event. For example, based on some pre-specified evaluability criteria, the investigator may classify the responses into three categories of “worsening,” “no change,” “and improving.”

Thus, the comparison of the two treatments is conducted based on the proportions of responses for different categories. A simple approach to analyzing these ordered categorical data is to create dichotomies among the levels of the response variable by combining observations from adjacent categories. For example, the two categories “worsening” and “no change” are amalgamated into a single category as “not improving.” The resulting data would be considered as binary responses classified as “improving” and “not improving,” which can be analyzed using a standard logistic regression model. This approach of collapsing (or ignoring) some categories of responses into a single category would certainly result in a loss of information and may lead to a considerable loss of statistical power. In addition, it is a concern that a pattern of results where the active treatment increased both the proportion of failures (“worsening”) as well as the proportion of successes (“improvement”) would be statistically significant and difficult to interpret.

Testing of the one-sided alternative hypothesis that the active treatment is better than the standard therapy for ordered categorical data can be done by using an exact conditional test when the sample size is moderate. The idea is to use a multinomial model to describe the probabilities of the responses falling into the various categories. Then, the comparison of the effectiveness of the two treatments is conducted by a conditional test, which requires the evaluation of all sample points to determine the conditional p -value. More details can be found in Agresti.^[1] More recent discussion of this approach can be found in Cohen and Sackrowitz.^[2] Although this approach does not rely on any asymptotic approximation to derive the distribution of the corresponding test statistic, it is not very efficient in terms of computing time for large sample size. When the sample size is large, several methods utilizing chi-square statistic have been proposed in the literature.^[3–5] In particular, Silvapulle and Sen^[6] gave a comprehensive review and discussion of the related ideas.

Recently, Chow et al.^[7] proposed to model the response probabilities via a parametric form and the comparison of these probabilities is translated into the comparison of the associated model parameters. Based on their approach, the maximum likelihood estimates (MLE) of the parameters can be obtained. Furthermore, a likelihood ratio test can be used to compare the effectiveness of the two treatments. Based on the asymptotic normality of the MLE of the parameters, the required sample size to achieve a given level of power to assess the difference between two treatments can be derived.

The major objective of this entry is to summarize the ideas discussed in Chow et al.^[7] and demonstrate the application of their methods through the analysis of three real data sets. The next section briefly outlines, the proposed model and the corresponding assumptions. Under the proposed model, results of a likelihood ratio test to assess treatment effect for ordered categorical data

and the corresponding required sample size to achieve a given level of power are derived. The section “Numerical Results” summarizes the results of a numerical study conducted for the determination of the required sample sizes under different combinations of response probabilities for the ordered categories. Examples concerning clinical trials for comparing a test treatment with an active control are presented in the section “Examples” to illustrate the use and interpretation of the proposed test. Some concluding remarks are given in the last section.

MODEL AND ASSUMPTIONS

Suppose that there are two types of treatment administered to the subjects and the corresponding response of the subject after receiving the treatment can be classified into k different categories. Denote the probability that the response falls into the j th category after receiving the i th treatment by π_{ij} . Consider the following model

$$\log \frac{\pi_{ij}}{\pi_{ik}} = \alpha_j + \beta_i, \quad i = 0, 1; j = 1, 2, \dots, k-1, \quad (1)$$

where α_j denotes the effect of the j th category relative to the k th category and β_i is the effect of the i th treatment. Note that $\pi_{ik} = 1 - \sum_{j=1}^{k-1} \pi_{ij}$. Model (1) can be expressed as $\frac{\pi_{ij}}{\pi_{ik}} = e^{\alpha_j + \beta_i}$. This gives

$$\pi_{ik} = \frac{1}{1 + e^{\alpha_1 + \beta_i} + e^{\alpha_2 + \beta_i} + \dots + e^{\alpha_{k-1} + \beta_i}} \quad (2)$$

and

$$\pi_{ij} = \frac{e^{\alpha_j + \beta_i}}{1 + e^{\alpha_1 + \beta_i} + e^{\alpha_2 + \beta_i} + \dots + e^{\alpha_{k-1} + \beta_i}}. \quad (3)$$

The logit model defined in Eq. (1) for the modeling of response probabilities of ordered categorical responses has been discussed extensively in the literature. Related details and further references can be found in Agresti.^[1] Under model (1), the difference between the two treatments is described by the difference between the parameters β_0 and β_1 . Thus, testing of no treatment difference can be assessed by the testing the hypotheses $H_0: \beta_0 = \beta_1$ vs $H_a: \beta_0 \neq \beta_1$. Let $\beta = \beta_1 - \beta_0$. Then, testing the above hypotheses is equivalent to testing the following hypotheses

$$H_0: \beta = 0 \text{ vs } H_a: \beta \neq 0. \quad (4)$$

The alternative hypothesis can be divided into the following two one-sided hypotheses:

$$H_{a1}: \beta < 0, \text{ and } H_{a2}: \beta > 0.$$

In general, if the responses are classified into k ordered categories, it can be shown that H_{a1} and H_{a2} are equivalent to the hypotheses $H'_{a1}: \pi_{0j} > \pi_{1j}, j = 1, \dots, k-1$ and $\pi_{0k} < \pi_{1k}$, and $H'_{a2}: \pi_{0j} < \pi_{1j}, j = 1, \dots, k-1$ and $\pi_{0k} > \pi_{1k}$ respectively. However, in many applications, the objective is to assess whether a test treatment is more effective than the existing treatment. Thus, the alternative hypothesis is often one-sided rather than two-sided. In other words, the hypotheses under testing are $H_0: \beta = 0$ vs $H_a: \beta < 0$.

Likelihood Ratio Test

Suppose that the two treatments are administered to N_0 and N_1 randomly selected subjects respectively. Let $n_{01}, n_{02}, \dots, n_{0k}$ and $n_{11}, n_{12}, \dots, n_{1k}$ be the corresponding observed frequencies falling into the k categories. Note that $\sum_{j=1}^k n_{ij} = N_i, i = 0, 1$. Denote the parameter vector $\theta = (\beta, \alpha_1, \alpha_2, \dots, \alpha_{k-1})$. The likelihood function is given by $L(\theta) = \prod_{i=0}^1 \prod_{j=1}^k \pi_{ij}^{n_{ij}}$ and the corresponding log-likelihood function is

$$\log L(\theta) = \sum_{i=0}^1 \sum_{j=1}^k n_{ij} \log \pi_{ij}. \quad (5)$$

Then, the MLE $\hat{\theta} = (\hat{\beta}, \hat{\alpha}_1, \hat{\alpha}_2, \dots, \hat{\alpha}_{k-1})$ of θ can be found by maximizing the log-likelihood function given in Eq. (5). The likelihood equations are obtained by setting the partial derivative of the log-likelihood function defined in Eq. (5) with respect to the parameters to 0. In particular,

$$\frac{\partial \log L(\theta)}{\partial \beta} = N_1 \pi_{1k} - n_{1k} = 0 \quad (6)$$

$$\frac{\partial \log L(\theta)}{\partial \alpha_j} = \sum_{i=0}^1 (n_{ij} - N_i \pi_{ij}) = 0; j = 1, 2, \dots, k-1.$$

Then, the MLE $\hat{\theta} = (\hat{\beta}, \hat{\alpha}_1, \hat{\alpha}_2, \dots, \hat{\alpha}_{k-1})$ of θ can be found by solving the k likelihood equations given in (6).

Alternatively, under $H_0: \beta = 0$, the likelihood function is $L_0(\alpha_1, \alpha_2, \dots, \alpha_{k-1}) = \prod_{j=1}^k \pi_j^{(n_{0j} + n_{1j})}$, or equivalently, the log-likelihood function is given by

$$\log L_0(\alpha_1, \alpha_2, \dots, \alpha_{k-1}) = \sum_{j=1}^k (n_{0j} + n_{1j}) \log \pi_j, \quad (7)$$

where $\pi_j = e^{\alpha_j} / (1 + e^{\alpha_1} + e^{\alpha_2} + \dots + e^{\alpha_{k-1}})$ for $j = 1, 2, \dots, k-1$ and $\pi_k = 1 - \sum_{j=1}^{k-1} \pi_j$. Taking partial derivatives of the log-likelihood function given in Eq. (7) with respect to the unknown parameters $\alpha_j, j = 1, \dots, k-1$, the corresponding likelihood equations are given as

$$\frac{\partial \log L_0(\alpha_1, \alpha_2, \dots, \alpha_{k-1})}{\partial \alpha_j} = \sum_{i=0}^1 (n_{ij} - N_i \pi_j) = 0; j = 1, 2, \dots, k-1. \quad (8)$$

Denote the MLE of $\theta = (\beta, \alpha_1, \alpha_2, \dots, \alpha_{k-1})$ under H_0 by $\hat{\theta}_0 = (0, \hat{\alpha}_1, \hat{\alpha}_2, \dots, \hat{\alpha}_{k-1})$. Then $\hat{\alpha}_j$ can be found by solving the likelihood equations given in Eq. (8).

Based on these results, a likelihood ratio test for the hypotheses Eq. (4) can be developed by taking the difference of the log-likelihood functions under the two hypotheses. In particular, $-2[\log L_0(\hat{\theta}_0) - \log L(\hat{\theta})]$ is asymptotically chi-square distributed with one degree of freedom when N_0 and N_1 are sufficiently large.^[8]

Determination of Sample Size

In practice, it would be of interest to determine the number of subjects required in a clinical study so that the test for the hypotheses given in Eq. (4) is with a given level of power $(1-\xi)$. To achieve this, the asymptotic distribution of the MLE of the parameter β is considered. Note

$$E\left(\frac{\partial^2 \log L}{\partial \alpha_j^2}\right) = -\sum_{i=0}^1 N_i \pi_{ij} (1 - \pi_{ij}); j = 1, 2, \dots, k-1,$$

$$E\left(\frac{\partial^2 \log L}{\partial \beta \partial \alpha_j}\right) = -N_1 \pi_{1j} \pi_{1k}; j = 1, 2, \dots, k-1,$$

$$E\left(\frac{\partial^2 \log L}{\partial \alpha_l \partial \alpha_j}\right) = \sum_{i=0}^1 N_i \pi_{il} \pi_{ij}; l, j = 1, 2, \dots, k-1 \text{ and } l \neq j.$$

Thus, the Fisher information matrix is $I(\theta) = -E(\partial^2 \log L / \partial \theta \partial \theta^T)$. Partition $I(\theta)$ into $\begin{pmatrix} a & I_{12} \\ I_{12}^T & I_{22} \end{pmatrix}$, where $a = N_1 \pi_{1k} (1 - \pi_{1k})$, $I_{12} = (N_1 \pi_{11} \pi_{1k} \ N_1 \pi_{12} \pi_{1k} \dots N_1 \pi_{1,k-1} \pi_{1k})_{1 \times (k-1)}$ and

$$I_{22} = \begin{pmatrix} \sum_{i=0}^1 N_i \pi_{i1} (1 - \pi_{i1}) & -\sum_{i=0}^1 N_i \pi_{i1} \pi_{i2} & \dots & -\sum_{i=0}^1 N_i \pi_{i1} \pi_{i,k-1} \\ -\sum_{i=0}^1 N_i \pi_{i1} \pi_{i2} & \sum_{i=0}^1 N_i \pi_{i2} (1 - \pi_{i2}) & \dots & -\sum_{i=0}^1 N_i \pi_{i2} \pi_{i,k-1} \\ \vdots & \vdots & \ddots & \vdots \\ -\sum_{i=0}^1 N_i \pi_{i,k-1} \pi_{i1} & -\sum_{i=0}^1 N_i \pi_{i,k-1} \pi_{i2} & \dots & \sum_{i=0}^1 N_i \pi_{i,k-1} (1 - \pi_{i,k-1}) \end{pmatrix}_{(k-1) \times (k-1)}.$$

that the Fisher information matrix can be found by taking the expected values of the negative of the second order partial derivatives of the log-likelihood function $\log L(\theta)$ with respect to the model parameters. In particular, from Eqs. (2) and (3), it is easy to show that

$$\frac{\partial \pi_{0j}}{\partial \beta} = 0, \quad \frac{\partial \pi_{1j}}{\partial \beta} = \pi_{1j} \pi_{1k}, j = 1, 2, \dots, k-1; \text{ and}$$

$$\frac{\partial \pi_{1k}}{\partial \beta} = -\pi_{1k} (1 - \pi_{1k});$$

$$\frac{\partial \pi_{ij}}{\partial \alpha_j} = \pi_{ij} (1 - \pi_{ij}), i = 0, 1; j = 1, 2, \dots, k-1;$$

$$\frac{\partial \pi_{il}}{\partial \alpha_j} = -\pi_{il} \pi_{ij}, i = 1, 0; j = 1, 2, \dots, k-1;$$

$$l = 1, 2, \dots, k \text{ and } l \neq j.$$

Observe that $E(n_{ij}) = N_i \pi_{ij}, i = 0, 1; j = 1, 2, \dots, k$. Using these results, the expected values of the second order partial derivatives of the log-likelihood function with respect to the parameters are:

$$E\left(\frac{\partial^2 \log L}{\partial \beta^2}\right) = -N_1 \pi_{1k} (1 - \pi_{1k}),$$

The asymptotic variance of the MLE $\hat{\beta}$ of β is given by

$$V = \frac{1}{a} \left[1 + \frac{1}{a} I_{12} \left(I_{22} - \frac{1}{a} I_{12}^T I_{12} \right)^{-1} I_{12}^T \right]. \quad (9)$$

It can be shown that $\hat{\beta}$ is asymptotically normally distributed with mean β and variance V when N_0 and N_1 are sufficiently large.^[9] Let V_0 and V_1 be the value of V given in Eq. (9) evaluated at $\hat{\theta}_0 = (0, \hat{\alpha}_1, \hat{\alpha}_2, \dots, \hat{\alpha}_{k-1})$ and $\hat{\theta} = (\hat{\beta}, \hat{\alpha}_1, \hat{\alpha}_2, \dots, \hat{\alpha}_{k-1})$ respectively. In particular, if the numbers of subjects assigned to the two treatments are the same, i.e., $N_0 = N_1 = N$. Denote $D_0 = NV_0$ and $D_1 = NV_1$. Based on the asymptotic normality of the MLE $\hat{\beta}$, the required sample size N to enable the test to have power $(1-\xi)$ to detect a difference $\Delta\beta$ in is given by the following expression,

$$N \geq \frac{(\sqrt{D_0} Z_\alpha - \sqrt{D_1} Z_{1-\xi})^2}{(\Delta\beta)^2}. \quad (10)$$

NUMERICAL RESULTS

In order to provide some insight on the pattern of required sample size to achieve a given level of power, seven sets of various combinations of π_{ij} are considered which

represent various cases occurring in the comparison of two medical treatments. More specifically, the cases $(\pi_{01}, \pi_{02}, \pi_{03}) = (0.1, 0.2, 0.7)$ and $(0.1, 0.4, 0.5)$ indicate that the effect of the existing treatment is significant (i.e. π_{03} is much larger than π_{01}) with the probability of the category “no change” is set to be relatively small and large respectively. Similarly $(\pi_{01}, \pi_{02}, \pi_{03}) = (0.4, 0.1, 0.5)$ and $(0.3, 0.4, 0.3)$ indicate that the effect of the existing treatment is not significant while the probability of the category “no change” is set to be relatively small and large respectively. The case $(\pi_{01}, \pi_{02}, \pi_{03}) = (0.33, 0.34, 0.33)$ indicates that the effect of the existing treatment is not significant. The cases $(\pi_{01}, \pi_{02}, \pi_{03}) = (0.6, 0.3, 0.1)$ and $(0.1, 0.3, 0.6)$ indicate that strong negative effect and strong positive effect of the existing treatment respectively.

Furthermore, for a given set $(\pi_{01}, \pi_{02}, \pi_{03})$, the effect of the test treatment is determined by considering $\pi_{01} > \pi_{11}$ and $\pi_{03} < \pi_{13}$, which indicate that the effect of the test treatment is better. Also, three different power levels are considered, namely, 0.65, 0.8, and 0.9, which represents the low, the medium and the high levels of power respectively. Based on Eqs. 9 and 10, the sample size N to achieve the desired level of power is computed. The results are presented in Table 1.

In general, for each given case, the sample size increases as the level of power increases. Moreover, the sample sizes for the first two cases are much smaller than those for the last two cases. The first two cases represent that the effect of the test treatment is significantly better than the existing treatment. That is, $\Delta\beta$ is large. Thus, even a sample of size 80

and 60 can achieve power 0.9 respectively. However, for the next two cases, a sample of size 818 and 1057 respectively is needed to achieve the same power since the difference between two treatments is very small. Thus, a much larger sample size is needed to detect the difference. Table 1 also lists the required sample sizes for different combinations of response probability in the four categories case. It can be seen that similar patterns emerge in the four categories case. Note that the sample sizes listed in Table 1 are derived based on asymptotic approximation. Chow et al^[7] conducted a simulation study to assess the performance of these results and the simulated powers are close to, and larger than in most cases, the corresponding nominal power.

EXAMPLES

In this section, three data sets are selected and analyzed for the purpose of demonstrating the testing results given in the previous sections.

Example 1

A study was conducted to compare two treatments for ulcer and a total of 64 subjects were enrolled in the study.^[10] Qualified subjects were randomized in a 1:1 ratio into the test treatment group and a control group. Subjects were classified into three ordered categories, namely “worsening,” “no change,” “improvement,” according to the change in the size of ulcer crater. A subject was considered

Table 1 Sample Size Required to Achieve the Nominal Level of Power

Probability of categories		Nominal power		
		0.65	0.80	0.90
i. Three categories				
$(\pi_{01}, \pi_{02}, \pi_{03}) = (0.10, 0.20, 0.70)$	$(\pi_{11}, \pi_{12}, \pi_{13}) = (0.04, 0.08, 0.88)$	35	55	80

improvement if the size of ulcer crater is greater than 2/3 healed or completely healed. A subject was considered worsening if the size of ulcer crater is larger than before. A subject was considered no change if the size of ulcer crater is less than 1/3 healed. The numbers of subjects observed in the test treatment group for the three categories are 5, 8, and 19, respectively, while the proportions of subjects observed in the control group for the three categories are 12, 10, and 10, respectively. The first category indicated “worsening” whilst the second and third categories indicated “no change” and “improvement” respectively.

Based on these observed frequencies from the two groups, the hypotheses $H_0: \beta = 0$ vs $H_a: \beta < 0$ are tested to assess whether the test treatment is more effective in treating the disease. In particular, the MLE of $\theta = (\beta, \alpha_1, \alpha_2)$ under H_0 is found to be $\hat{\theta}_0 = (0, \tilde{\alpha}_1, \tilde{\alpha}_2) = (0, -0.5341, -0.4769)$, while the MLE of $\theta = (\beta, \alpha_1, \alpha_2)$ under H_1 is equal to $\hat{\theta} = (\tilde{\beta}, \tilde{\alpha}_1, \tilde{\alpha}_2) = (-1.1679, 0.0663, 0.1235)$. The test statistic $-2[\log L_0(\hat{\theta}_0) - \log L(\hat{\theta})]$ is evaluated and is found to be 5.18, which is significant when compared to the lower 5% value of a chi-square distribution with one degree of freedom. In other words, there is enough evidence to show that the test treatment is more effective in treating the disease, i.e., the response probability of falling into category “improving” is higher than that of the other treatment.

Example 2

A clinical trial was conducted for the evaluation of efficacy of a test treatment (intravenous infusion) to treat subjects who experienced moderate to severe Crohn’s disease that was refractory to steroids and immunosuppressant. A total of 120 subjects were enrolled in this study. Qualified subjects were randomized in a 1:1 ratio into the test treatment group and a control group. Subjects received treatment on days 0, 14, and 28. The primary endpoint considered in this clinical study was the crohns disease activity index (CDAI) score at Day 42. Subjects were classified into three ordered categories where the first category indicated “worsening” whilst the second and third categories indicated “no change” and “improvement” respectively, depending upon the CDAI score at Day 42. A subject was considered a responder (improvement) if there is a decrease from baseline of at least 70 points in CDAI at Day 42. A subject was considered worsening if his/her CDAI score increases at Day 42. A subject was considered no change if his/her CDAI score is not considered worsened or improved. The numbers of subjects observed in the test treatment group for the three categories are 9, 36, and 15, respectively, while the proportions of subjects observed in the control group for the three categories are 12, 39, and 9, respectively.

Suppose that model (1) is used to model the response frequencies of the various categories. Based on these observed frequencies from the two groups, the hypotheses $H_0: \beta = 0$ vs $H_a: \beta < 0$ are tested to assess whether

the test treatment is more effective in treating the disease. In particular, the MLE of $\theta = (\beta, \alpha_1, \alpha_2)$ under H_0 is found to be $\hat{\theta}_0 = (0, \tilde{\alpha}_1, \tilde{\alpha}_2) = (0, -0.1335, 1.1394)$ whereas the MLE of $\theta = (\beta, \alpha_1, \alpha_2)$ under H_1 is equal to $\hat{\theta} = (\tilde{\beta}, \tilde{\alpha}_1, \tilde{\alpha}_2) = (-0.636, 0.2148, 1.4877)$. The test statistic $-2[\log L_0(\hat{\theta}_0) - \log L(\hat{\theta})]$ is evaluated and is found to be 1.89, which is insignificant when compared to the lower 5% value of a chi-square distribution with one degree of freedom. In other words, there does not exist significant evidence to conclude that the test treatment is more effective in treating the disease, i.e., the response probability of falling into category “improving” is not higher than that of the other treatment.

Example 3

This study was to compare four treatments on the extent of trauma due to subarachnoid hemorrhage.^[11] For illustration purpose, two out of the four treatments were selected for comparison, namely, “Placebo” (control) and “Low dose” (treatment). A total of 400 subjects were enrolled in this study. 190 and 210 qualified subjects were randomly allocated into the test treatment group and a control group, respectively. Subjects were classified into four ordered categories, namely “Death,” “Vegetative state,” “Major disability,” “Recovery” (including minor disability and good recovery), according to the outcome after the treatments. The numbers of subjects observed in the four ordered categories for the test treatment group were 48, 21, 44, and 77, respectively, whereas the proportions of subjects observed in the four categories for the control group were 59, 25, 46, and 80, respectively.

Based on these observed frequencies from the two groups, the hypotheses $H_0: \beta = 0$ vs $H_a: \beta < 0$ were tested to assess whether the test treatment is more effective in treating the disease. In particular, the MLE of $\theta = (\beta, \alpha_1, \alpha_2, \alpha_3)$ under H_0 were found to be $\hat{\theta}_0 = (0, \tilde{\alpha}_1, \tilde{\alpha}_2, \tilde{\alpha}_3) = (0, 0.1387, -0.5053, -0.5911)$, where as the MLE of $\theta = (\beta, \alpha_1, \alpha_2, \alpha_3)$ under H_1 is equal to $\hat{\theta} = (\tilde{\beta}, \tilde{\alpha}_1, \tilde{\alpha}_2, \tilde{\alpha}_3) = (-0.1019, -0.3347, -1.1789, -0.5077)$. The test statistic $-2[\log L_0(\hat{\theta}_0) - \log L(\hat{\theta})]$ was evaluated and found to be 36.67, which is significant when compared to the lower 5% value of a chi-square distribution with one degree of freedom. In other words, there is enough evidence to show that the test treatment is more effective in treating the disease, i.e., the response probability of falling into category “Recovery” is higher than that of the other treatment.

CONCLUSION

This entry has considered the problem of comparing the effectiveness of two treatments based on categorical responses. Instead of using a multinomial model to describe the probabilities of the responses falling into the various categories and comparing the effectiveness of the

two treatments by a conditional test, we have presented an alternative approach to model the response probabilities via a parametric form and the comparison of these probabilities is translated into the comparison of the associated model parameters. Maximum likelihood estimates (MLE) of the parameters are derived and the comparison is based on a chi-squared test. Furthermore, the required sample size to achieve a given level of power to detect the difference is also given. Furthermore, three data sets are selected and analyzed based on the derived results as an illustration. Although the discussion of the example and the numerical results given are based on only three or four categories, it can be easily extended to cases with more than four categories. In general, this approach is more efficient in computing time and provides a viable tool for practitioners to assess whether a new treatment is more effective than another treatment when the responses are categorical.

Abstract

Ordered Multiple Class Receiver Operating Characteristic (ROC) Analysis The receiver operating characteristic curve (ROC) is a graphical representation resulting from plotting the proportion of diseased subjects with a positive test result vs. the proportion of healthy subjects with a positive test that result from considering all possible values of a diagnostic test used as a cutoff. This entry provides a detailed definition of a ROC curve and supplies a sample application.

Keywords: Bootstrap; Classification; Diagnostic testing; ROC analysis; ROC curves; True class rate; U-statistics.

INTRODUCTION

Assessment of diagnostic markers for classification and prediction in two-class classification problems is commonly performed with the use of receiver operating characteristic (ROC) curves. The two classes under study are commonly referred to as the diseased and healthy populations. The ROC curve is a graphical representation resulting from plotting the proportion of diseased subjects with a positive test result (TPR, true positive rate) vs. the proportion of healthy subjects with a positive test (FPR, false positive rate) that result from considering all possible values of a diagnostic test used as a cutoff. The area under the ROC curve (AUC) is used as a global measure of the test's discriminatory accuracy between the two groups. Estimation of the AUC and its standard error is performed by non-parametric methods and parametric means.^[1] In three-class diagnostic problems three true class rates (TCR) are defined using an appropriate classification criterion. Extension to multiple-class problems is straightforward. In the three-class case, an ROC surface is generated in three dimensions by considering all possible diagnostic test values. The volume under the ROC surface (VUS) can be used as a global measure of the three-class discriminatory ability of the test under consideration. Estimation and inference involving the VUS are also done in a manner similar to the estimation of the two-dimensional AUC. The VUS can be used whenever the diagnostic marker measurements are continuous or comprised of ordered categories (ordinal data).

ROC SURFACE DEFINITION AND CONSTRUCTION

Roc Curve Definition and Construction

ROC curves are commonly used for the evaluation of diagnostic markers in two-class testing. Let $X_{11}, \dots, X_{1m}$ be m measurements obtained from the first class and $X_{21}, \dots, X_{2n}$ be n measurements from the second class. For example, these two classes may involve healthy patients or patients having a certain disease. Without loss of generality, suppose that subjects from the first class tend to have lower measurements than subjects from the second class. The ROC curve is defined as the set of points $(FPR(c), TPR(c))$ in the unit square, for all possible values of c , where $TPR(c) = P(X_2 > c)$ and $FPR(c) = P(X_1 > c)$ signify the probability that a diseased and a healthy patient, respectively, will have a positive test defined at the threshold point c . The TPR is the familiar concept of sensitivity of a test. An equivalent construction of the ROC curve is defined by the set of points $(TNR(c), TPR(c))$ in the unit square, where $TNR(c) = P(X_1 < c)$ is the probability that a healthy subject will have a negative test. This is the specificity of a test. The AUC is used as an overall performance index of the diagnostic accuracy of a marker, and it is equal to $P(X_1 < X_2)$. That is, the AUC is the average chance that the test score of a randomly selected subject from the first (healthy patient) group will be lower than the score of a randomly selected subject from the second (diseased patient) group. The AUC derived from a noninformative marker is 0.5 (implying that

the test resulting from this marker is no better than the flip of a coin). Conversely, the AUC resulting from a perfectly discriminating marker is 1.0 (that is, a randomly selected pair of observations from the healthy and diseased groups will always have the correct ordering of marker values). The interested reader should review Refs. [1–3], some recent textbooks on ROC curve methodology.

The Roc Surface And Hypersurface

Efforts to generalize the utility of the ROC curve for the assessment of diagnostic markers in multigroup classification problems have led to a number of approaches for the extension of ROC curve theory.^[4–10] The difficulty in generalizing the ROC curve to more than two classes results from the fact that a decision rule for a K -group classification will produce K true classification rates (TCR) and $K \times (K - 1)$ false classification rates (FCR), where $TCR_k = P(C = k|D = k)$, $k = 1, \dots, K$ and $FCR_{ij} = P(C = i|D = j)$, $i, j = 1, \dots, K$, $i \neq j$, D is the true class membership of an individual while C is the class assigned by the testing procedure. A concise graphical representation of such a decision rule is the K -dimensional ROC hypersurface that can be used for the assessment of the diagnostic capacity of the marker under study.

For the sake of simplicity we illustrate first how an ROC surface is generated from a three-group classification problem based on a diagnostic marker X . Fig. 1 depicts a hypothetical situation for the distributions of marker measurements X_1 , X_2 , and X_3 obtained from three classes where, in general, measurements from class 1 are lower than those from class 2, and measurements from class 2 are lower than those from class 3. A decision rule that classifies subjects in one of these three classes can be defined as follows: For two ordered threshold points $c_1 < c_2$ (Fig. 1).

IF marker value $X < c_1$ THEN assign subject to class 1
ELSE IF $c_1 < X < c_2$ THEN assign to class 2
ELSE assign to class 3

In practice ties between measurements and threshold values may occur. In that case, the less than signs “<” above can arbitrarily be replaced with less than or equal signs “≤” as

Fig. 1 Hypothetical overlapping distributions of marker measurements in a three-class experiment

long as the sets defined by the decision rule remain disjoint (i.e., no subject can be classified as being a member of more than one group). Varying the ordered decision thresholds $c_1 < c_2$ over all possible marker measurements, TCR are defined. These can be plotted in three dimensions to produce an ROC surface in the unit cube $[0,1] \times [0,1] \times [0,1]$. The TCR take values with corner coordinates $\{(1,0,0), (0,1,0), (0,0,1)\}$. This construction is a direct generalization of the ROC curve in three dimensions because ignoring c_2 and the subrules that this implies a conventional ROC curve between classes 1 and 2 is constructed. Similarly, ignoring c_1 results in an ROC curve between classes 2 and 3.

In the case of continuous or ordered categorical (ordinal) data, if the distributions of the marker values for the three groups are $X_1 \sim F_1$, $X_2 \sim F_2$, and $X_3 \sim F_3$, the theoretical TCR are defined by $F_1(c_1)$, $F_2(c_2) - F_2(c_1)$, and $1 - F_3(c_2)$, respectively, for all possible values of c_1, c_2 , with $c_1 < c_2$. The ROC surface is constructed by plotting the points $(F_1(c_1), F_2(c_2) - F_2(c_1), 1 - F_3(c_2))$ in three dimensions. In practice, the empirical cumulative distribution functions are used. These are defined from the data as the proportion of subjects in each group that are below the threshold c . For example, based on n_1 observations from the first class, the empirical cumulative distribution estimate of F_1 is defined as $\hat{F}_1(c) = \sum_{i=1}^{n_1} I(X_i < c) / n_1$ where $I(X_i < c)$ is the indicator function and is equal to 1 if observation $X_i < c$, and 0 otherwise. Fig. 2 shows an empirical ROC surface with marker measurements simulated from three different, overlapping normal distributions. The theoretical VUS constructed by the decision rule described above is equal to the probability that three random measurements, one from each class, are classified in the correct order $X_1 < X_2 < X_3$. That is, $VUS = P(X_1 < X_2 < X_3)$. This is a straightforward generalization of the two-dimensional ROC curve. An unbiased non-parametric estimator of VUS is given by

Fig. 2 ROC surface for measurements sampled from the three hypothetical distributions of Fig. 1

$$VUS = \frac{1}{n_1 n_2 n_3} \sum_{i=1}^{n_1} \sum_{j=1}^{n_2} \sum_{k=1}^{n_3} I(X_{1i}, X_{2j}, X_{3k})$$

where n_1 , n_2 , and n_3 are the sample sizes from classes 1, 2, and 3, respectively, and $I(X_1, X_2, X_3)$ equals 1 if X_1, X_2 , and X_3 are in the correct order, and 0 otherwise. In practice, ties between measurements may occur. In that case we define

$$I(X_1, X_2, X_3) = \begin{cases} 1 & X_1 < X_2 = X_3 \\ 1/2 & X_1 < X_2 = X_3 \text{ or } X_1 = X_2 < X_3 \\ 1/6 & X_1 = X_2 = X_3 \\ 0 & \text{otherwise} \end{cases}$$

When the diagnostic marker is completely uninformative, i.e., when there is perfect overlap between the distributions of the three classes, VUS takes the value 1/6 (that is, classification into three groups using that marker is no better than random chance). Conversely, perfect separation between the three classes with $X_1 < X_2 < X_3$ for all measurements yields $VUS = 1$. Parametric modeling of the ROC surface and estimation of the respective VUS has also been developed.^[5,11]

Generalization to K -class ($K > 3$) is straightforward. An ROC hypersurface can be constructed (but not visualized) by defining a diagnostic rule with $K - 1$ ordered decision thresholds. The K TCR thus defined should be plotted in a K -dimensional space. The ROC hypersurface is produced by varying the $K - 1$ ordered decision thresholds and calculating the respective TCR. A non-parametric unbiased estimate of the volume under the hypersurface is given by

$$VUS = \frac{1}{n_1 n_2 \dots n_k} \times \sum_{i_1=1}^{n_1} \sum_{i_2=1}^{n_2} \dots \sum_{i_k=1}^{n_k} I(X_{1i_1}, X_{2i_2}, \dots, X_{ki_k})$$

where n_i , $i = 1, 2, \dots, K$ are the sample sizes from classes 1, 2, ..., K , respectively, and $I(X_{1i_1}, X_{2i_2}, \dots, X_{ki_k})$ is defined in analogy to the three-class case. The VUS under this hypersurface takes the value 1 when there is perfect separation between the K -classes in the desired order, and it takes the value $1/(k!)$ when the K -class classification test is uninformative. The variance of the VUS can be calculated based on U-statistics theory or bootstrap techniques.^[10] This can be used to produce $(1 - \alpha)\%$ confidence intervals and perform statistical inference.^[10,12]

Construction of non-parametric umbrella ROC graphs and estimation of the respective umbrella volume (UV), appropriate in studies where the ordering of interest is $X_1 < X_3 > X_2$, or $X_2 > X_1 < X_3$ is discussed in Ref. [13].

AN APPLICATION

Glial cells are found in the central nervous system. They provide structural support and protection for neurons. When neurons are injured, glial cells form a fibrous network

in the area of injury. The resulting “gliosis” is prominent in a number of conditions that damage the central nervous system such as multiple sclerosis and stroke. In particular, gliosis has been found in neuropathology studies of injury to the central nervous system resulting from infection with the human immunodeficiency virus (HIV).^[14] Myoinositol (MI) is a marker of glial cells in the brain.^[15] Its levels can be measured by an imaging technique called magnetic resonance spectroscopy (MRS). Increased levels of MI, or its ratio over another marker creatine (Cr) MI/Cr, particularly in the basal ganglia have been associated with neurological impairment resulting from HIV infection.^[16,17] MI/Cr measurements were assessed here as an illustration of a diagnostic tool for the discrimination of three subject groups: HIV-negative patients (NEG), HIV-positive patients neurologically asymptomatic (NAS), and HIV-positive patients with neurological impairment [AIDS Dementia Complex (ADC)]. Details of this study have been described in detail elsewhere.^[18,19] There are six possible orderings for MI/Cr measurements of the three classes, i.e., $NEG < NAS < ADC$, $NAS < NEG < ADC$, $NEG < ADC < NAS$, $NAS < ADC < NEG$, $ADC < NEG < NAS$, and $ADC < NAS < NEG$. The ROC surfaces corresponding to these orderings were constructed, and the volumes under these ROC surfaces were estimated to be 0.4299, 0.2090, 0.1542, 0.0867, 0.0647, and 0.0556, respectively. These results indicate that the strongest evidence supports an increasing trend in the MI/Cr measurements of the HIV-negative subjects, HIV-positive asymptomatic patients, and HIV-positive patients with neurological impairment. Fig. 3 shows the corresponding ROC surface. A 95% confidence interval for the corresponding VUS is (0.328, 0.5318) based on the U-statistics methodology described in Refs. [10,12]. Because the uninformative value of 1/6 for a three-class VUS is excluded from the 95% confidence interval, the implication is that MI/Cr measured via MRS in the basal ganglia is informative

Fig. 3 ROC surface for MI/Cr in the basal ganglia measurements for the classification $NEG < NAS < ADC$

for the classification of subjects in the NEG, NAS, and ADC classes. In addition, when three measurements are given, one from each class, the probability that the MI/Cr level obtained from an HIV-negative subject is lower than that of the one obtained from an HIV-positive person and that both are lower than the MI/Cr levels measured in an individual suffering from HIV-related neurological impairment is estimated to be about 43% of the time.

CONCLUSIONS

Medical diagnostic tests often result in more than two classes. Traditional techniques such as ROC curve analysis can be generalized to three or more group classification problems by appealing to ROC surfaces in three or higher dimensions. In a similar manner, the area under the two-dimensional ROC curve, a global index of test accuracy, can be extended to three or higher dimensions by use of the VUS or hypersurface, respectively. We describe here non-parametric estimation of the VUS and use well-developed U-statistics methodology to derive estimates of the VUS along with confidence intervals. This formulation is useful especially when an inherent ordering exists in the marker measurements between the classes under study.

Because the relative size, rather than the absolute size, of the measurements is used, monotonic transformations of the measurement scale will result in the same estimated ROC surface and VUS in direct extension of this useful property of the two-dimensional ROC curve and AUC. In addition, the VUS defined above is the probability that the marker measurements from k ($k > 2$) subjects, one from each class, will be correctly ordered. This is a helpful interpretation, identical to the two-dimensional AUC. The VUS therefore maintains a number of useful properties of the two-dimensional ROC curve.

Thus, the described methodology addresses directly the question of the marker discriminatory performance over all the classes under study. Pairwise analysis of ROC curves can be performed in a post hoc manner as a detailed approach in multiple-class classification problems. In the example provided, measuring the VUS produced by MRS-measured MI/Cr levels shows that a strong trend exists between HIV-negative subjects, HIV-positive neurologically asymptomatic patients, and HIV-positive patients suffering from neurological complications associated with the infection. This observation has profound implications for the use of this marker in clinical diagnosis of HIV-associated neurological impairment as well as clinical consequences for our understanding of HIV-related neurological injury. Because MI/Cr levels of HIV-positive unimpaired patients were between those of HIV-negative and neurologically impaired subjects, the suggestion is that neurological injury occurs among

HIV-infected individuals well before clinical symptoms (leading to an ADC diagnosis) are observed.^[18,19] A three-class ROC surface analysis of these data therefore is a useful means of illuminating these relationships.

Ordinal Data: Crossover Design Analysis

Kung-Jong Lui

Department of Mathematics and Statistics, San Diego State University, San Diego, California, U.S.A.

Abstract

We may commonly encounter, in a crossover trial, the underlying patient response of interest on an ordinal scale—worse, same, slightly improved, and better. Since these ordinal responses are not continuous or interval data, the ordinal responses are generally not appropriate for arithmetic operation. We discuss the approaches to analyze ordinal data under a crossover design. These include the normal random effects proportional odds model, the simple change score method, and the conditional approach with using the generalized odds ratio to measure the relative treatment effects. We focus our discussion on the most frequently used AB/BA (or simple crossover) design. We present both asymptotic and exact test procedures, as well as asymptotic and exact interval estimators. We further extend the discussion to a three-treatment three-period crossover trial. We note that one can easily apply the ideas presented here to derive the corresponding test procedures and estimators when using a Latin squares to reduce the large number of groups for comparing four or more treatments in a crossover trial with a complete set of treatment-receipt sequences, or when employing an incomplete block crossover design to decrease the risk of being lost to follow-up in a crossover trial with long duration.

Keywords: Proportional odds model; Simple change score method; Generalized odds ratio; Ordinal data; Latin square; Incomplete block design.

INTRODUCTION

To save the number of patients or improve power of test procedures for a parallel groups design, the crossover design has been often employed to study non-curative treatments for chronic diseases. In randomized clinical trials, it is quite common to encounter the patient response on an ordinal scale. Because the relative distance between successive ordered categories are not truly comparable, ordinal data are generally inappropriate for arithmetic operations.^[1] For example, consider the AB/BA crossover trial conducted by 3 M Health Care Ltd to compare the suitability of two inhalation devices (A and B) among asthma patients using a standard inhaler device to deliver salbutamol.^[1] Patients were randomly assigned to either group 1 using device A for one week followed by device B for another week or group 2 using device B for one week followed by device A for another week. Patients were then requested to assess the clarity of leaflet instructions regarding devices on a four-point ordinal scale—“easy,” “only clear after rereading,” “not very clear,” and “confusing.” Since these ordinal levels of responses are not on an interval scale, the relative distance between “easy” and “only clear after rereading” is not, for example, comparable to that between “only clear after rereading” and “not every clear.” Although one may often arbitrarily assign scores, such as 0, 1, 2, 3, to

these ordinal categories and apply the t-test to test equality between treatments, providing a meaningful and easily understood summary measure based on these artificial scores to quantify the relative effect between treatments can be difficult.

Because of its simplicity, the use of the AB/BA design (or simple carry-over design) has accounted for a large proportion of crossover trials employed in practice.^[2–5] Thus, we concentrate our discussion on the development of analysis in ordinal data under the AB/BA trial. These include the normal random effects proportional odds model,^[1] the simple change score method,^[6] and the conditional approach^[7,8] with using the generalized odds ratio (GOR)^[9] to measure the relative treatment effects. Because it can be sometimes more appealing and economical to compare more than one experimental treatment with a placebo in a single trial instead of several trials, each having its own experimental and placebo arms, we extend the discussion to a three-treatment three-period crossover design.^[8] Also, because a crossover trial, in which each patient receives all treatments under comparison, can take a long time to implement especially when there are three or more treatments, we note that one can employ similar ideas as focused here to derive the test procedures and estimators under an incomplete block design.^[3] For comparing four or more treatments, we further note that it is

straightforward to develop the corresponding test procedures and estimators presented here when one uses the Latin square^[3] in a crossover trial to reduce the number of groups with different treatment-receipt sequences.^[8] Other methods to analyze ordinal data, such as the use of the log-linear model^[2] or Wilcoxon test, appear elsewhere.^[6,10]

We assume that there are no carry-over effects due to the treatment administered at an earlier period with an adequate wash-out period. If we cannot ensure this assumption of no carry-over effects with an adequate wash-out period to hold onto the basis of our subjective knowledge, as noted elsewhere,^[3,11,12] we may not want to use the crossover design. We consider the situations in which the underlying patient response is on an ordinal scale with J -ordered categories in ascending order.

AB/BA CROSSOVER DESIGN

Suppose that we compare an experimental treatment B with an active control treatment (or a placebo) A in a crossover trial. We randomly assign n_1 patients to group ($g =$) 1 with A-then-B sequence, in which patients receive treatment A at period 1 and then cross over to receive treatment B at period 2, and n_2 patients to group ($g =$) 2 with B-then-A sequence, in which patients receive treatment B at period 1 and then cross over to receive treatment A at period 2.

Normal Random Effects Proportional Odds Model

To account for the intraclass correlation between responses within patients and the period effect, Ezzet and Whitehead^[1] first proposed a normal random effects proportional odds model^[13,14] to analyze ordinal data. For patient i ($= 1, 2, \dots, n_g$) from group g ($= 1, 2$) at period z ($= 1, 2$), let $X_{iz}^{(g)} (= 1$ for the patient receiving the experimental treatment B at period z , and $= 0$, otherwise) and $Z_{iz}^{(g)} (= 1$ for period $z = 2$, and $= 0$, otherwise) denote the treatment and period covariates of this patient, respectively. We let $\mu_i^{(g)}$ denote the random effect due to the i th subject in group g , and assume $\mu_i^{(g)}$'s to be independent and identically distributed as a normal distribution with mean 0 and unknown variance σ^2 . We further let $Y_{iz}^{(g)} = j$ ($= 1, 2, \dots, J$) denote in group g the response of the i th patient at period z falling in the j th ordered category. We assume that the logit of the cumulative probability for a given patient response $Y_{iz}^{(g)}$ with $\mu_i^{(g)}$ fixed falling below (and including) the j th ($= 1, 2, 3, \dots, J - 1$) ordered category is:^[1,14]

$$\log \left(\frac{P(Y_{iz}^{(g)} \leq j | \mu_i^{(g)})}{P(Y_{iz}^{(g)} > j | \mu_i^{(g)})} \right) = \alpha_j + \beta_{BA} X_{iz}^{(g)} + \gamma Z_{iz}^{(g)} + \mu_i^{(g)} \quad (1)$$

where β_{BA} denotes the relative effect of treatment B to treatment A, and γ denotes the effect of period 2 vs. period 1. When there is no difference in effects between treatments

A and B, $\beta_{BA} = 0$. If the patient receiving treatment B tends, as compared with he/she receiving treatment A, to fall in lower categories for a given fixed period, then $\beta_{BA} > 0$. If the patient receiving treatment B tends, as compared with he/she receiving treatment A, to fall in higher categories for a fixed period, then $\beta_{BA} < 0$. Note that for a given fixed patient under model (Eq. 1), we have,

$$P(Y_{iz}^{(g)} \leq j | \mu_i^{(g)}) = \frac{\exp(\alpha_j + \beta_{BA} X_{iz}^{(g)} + \gamma Z_{iz}^{(g)} + \mu_i^{(g)})}{1 + \exp(\alpha_j + \beta_{BA} X_{iz}^{(g)} + \gamma Z_{iz}^{(g)} + \mu_i^{(g)})} \quad (2)$$

This implies that the probability for the patient response $Y_{iz}^{(g)}$ falling in the j th ($= 1, 2, 3, \dots, J$) ordered category is

$$P(Y_{iz}^{(g)} = j | \mu_i^{(g)}) = P(Y_{iz}^{(g)} \leq j | \mu_i^{(g)}) - P(Y_{iz}^{(g)} \leq j-1 | \mu_i^{(g)}) \quad (3)$$

where $P(Y_{iz}^{(g)} \leq 0 | \mu_i^{(g)}) = 0$ and $P(Y_{iz}^{(g)} \leq J | \mu_i^{(g)}) = 1$. Thus, the joint probability of $(Y_{i1}^{(g)} = j, Y_{i2}^{(g)} = j')$ for a randomly selected patient from group g is given by^[1]

$$P(Y_{i1}^{(g)} = j, Y_{i2}^{(g)} = j') = \int P(Y_{i1}^{(g)} = j | u) P(Y_{i2}^{(g)} = j' | u) f(u) du \quad (4)$$

where $f(u)$ is the probability density function of the assumed normal distribution for $\mu_i^{(g)}$. For simplicity, we let $\pi_{jj'}^{(g)}$ denote the probability $P(Y_{i1}^{(g)} = j, Y_{i2}^{(g)} = j')$. We define $n_{jj'}^{(g)}$ as the number of patients in group g ($= 1, 2$) falling in the cell with the response vector $(Y_{i1}^{(g)} = j, Y_{i2}^{(g)} = j')$ among n_g patients. The random frequencies $\{n_{jj'}^{(g)} | j = 1, 2, 3, \dots, J, j' = 1, 2, 3, \dots, J\}$ then follow the multinomial distribution with parameters n_g and $\{\pi_{jj'}^{(g)} | j = 1, 2, 3, \dots, J, j' = 1, 2, 3, \dots, J\}$. The likelihood is then proportional to:

$$\prod_{g=1}^2 \prod_{j=1}^J \prod_{j'=1}^J [P(Y_{i1}^{(g)} = j, Y_{i2}^{(g)} = j')]^{n_{jj'}^{(g)}} \quad (5)$$

which is involved in non-closed form of integrals (Eq. 4) and is required to use a sophisticated iterative numerical procedure. We can employ PROC GLIMMIX^[2,15] to obtain the maximum likelihood estimator (MLE) of parameters and the estimated asymptotic standard error (SE) of the MLE based on likelihood (Eq. 5). As noted elsewhere,^[9,16,17] however, the implicit assumption of the proportional odds model can be badly violated by many bivariate distributions. Also, we need to assume the random effects $\mu_i^{(g)}$ due to patients to follow a normal distribution for mathematical convenience when using PROC GLIMMIX. In practice, it is difficult to justify any distribution for the unobservable patient random effects. Furthermore, the number of patients is frequently small in a crossover trial and thereby the MLE can be inappropriate for use in small-sample cases. On the other hand, using the above normal random effects proportional odds model can

allow us to study whether there is a treatment-by-period interaction, and accommodate modeling a high-order or other crossover designs easily.

Simple Change Score Method

To alleviate the burden of employing a numerical iterative procedure to solve the likelihood equations and make the calculation be tractable, Senn^[6] proposed a simple change score approach by converting the base scores into a five-point scale. To illustrate Senn's idea, consider the above example regarding the assessment of the clarity of leaflet instructions between devices A and B on a four-point base scores, 0, 1, 2, 3, corresponding to the four-ordered categories "easy," "only clear after rereading," "not very clear," and "confusing." Using the difference in these base scores between periods within patients, Senn proposed classifying the score difference $\{-3\}$, $\{-2, -1\}$, $\{0\}$, $\{1, 2\}$, and $\{3\}$ as "much worse," "worse," "same," "better," and "much better," respectively. Based on these five-point change score scales, Senn then proposed that one could use various statistical methods for detecting trend effect to test equality of treatments. As noted by Ezzet and Whitehead,^[18] one of the main concerns in use of the simple change score method is to group patients with response changes that are not comparable into the same category. For example, all patients with base scores at two periods $\{(0, 1), (0, 2), (1, 2), (1, 3), (2, 3), (2, 4), (3, 4)\}$ would be grouped into the same "better" category. However, note that patients with responses changing from "easy" (coded as 0) to "not very clear" (coded as 2) is clearly different from patients with responses changing from "clear only after rereading" (coded as 1) to "confusing" (coded as 3). The above concern of grouping patients with incomparable extent of changes into the same category can exacerbate as the number of possible base scores for the original ordinal categories increases. In practice, we may wish to quantify the magnitude of the relative treatment effect. The development of a simple change score scheme to reflect the relative distance between different ordered levels and the creation of an easily appreciated summary measure of the relative treatment effect based on the change score method can be challenging.

Distribution-Free Random Effects Model with Using a Conditional Approach

We assume that the joint probability of $(Y_{i1}^{(g)}, Y_{i2}^{(g)})$ in group g for a given patient i ($=1, 2, \dots, n_g$) with $\mu_i^{(g)}$ fixed satisfies:^[19]

$$P(Y_{i1}^{(g)} < Y_{i2}^{(g)} | \mu_i^{(g)}) = \frac{1}{1 + \exp(\mu_i^{(g)} + \eta_{BA} X_{i1}^{(g)} + \gamma Z_{i1}^{(g)})} \times \frac{\exp(\mu_i^{(g)} + \eta_{BA} X_{i2}^{(g)} + \gamma Z_{i2}^{(g)})}{1 + \exp(\mu_i^{(g)} + \eta_{BA} X_{i2}^{(g)} + \gamma Z_{i2}^{(g)})}$$

$$P(Y_{i1}^{(g)} > Y_{i2}^{(g)} | \mu_i^{(g)}) = \frac{1}{1 + \exp(\mu_i^{(g)} + \eta_{BA} X_{i2}^{(g)} + \gamma Z_{i2}^{(g)})} \times \frac{\exp(\mu_i^{(g)} + \eta_{BA} X_{i1}^{(g)} + \gamma Z_{i1}^{(g)})}{1 + \exp(\mu_i^{(g)} + \eta_{BA} X_{i1}^{(g)} + \gamma Z_{i1}^{(g)})}$$

and

$$P(Y_{i1}^{(g)} = Y_{i2}^{(g)} | \mu_i^{(g)}) = 1 - P(Y_{i1}^{(g)} > Y_{i2}^{(g)} | \mu_i^{(g)}) - P(Y_{i1}^{(g)} < Y_{i2}^{(g)} | \mu_i^{(g)}) \quad (6)$$

where $\mu_i^{(g)}$'s are assumed to independently follow an unspecified probability density function $f_g(\mu)$, η_{BA} denotes the relative effect of treatment B to treatment A, and γ denotes the effect of period 2 vs. period 1. The GOR for paired-samples^[9,20,21] or Agresti's α' of responses on a given patient i in group g ($= 1, 2$) when the patient has covariates $(X_{i2}^{(g)}, Z_{i2}^{(g)})$ at period 2 vs. when he/she has covariates $(X_{i1}^{(g)}, Z_{i1}^{(g)})$ at period 1 under model (Eq. 6) is:

$$\frac{P(Y_{i1}^{(g)} < Y_{i2}^{(g)} | \mu_i^{(g)})}{P(Y_{i1}^{(g)} > Y_{i2}^{(g)} | \mu_i^{(g)})} = \exp(\eta_{BA} (X_{i2}^{(g)} - X_{i1}^{(g)}) + \gamma (Z_{i2}^{(g)} - Z_{i1}^{(g)})) \quad (7)$$

When there is no difference in effects between treatments A and B, $\eta_{BA} = 0$. When the response of the patient receiving treatment B tends to fall, for a given fixed period, in a category with higher than that of the patient receiving treatment A, $\eta_{BA} > 0$. When the response of the patient receiving treatment B tends to fall, for a given fixed period, in a category lower than that of the patient receiving treatment A, $\eta_{BA} < 0$. We define the GOR of responses for treatment B vs. treatment A as $\text{GOR}_{BA} = \exp(\eta_{BA})$. We let $\Pi_C^{(g)}$ and $\Pi_D^{(g)}$ denote for a randomly selected patient i from group g the probabilities $P(Y_{i1}^{(g)} < Y_{i2}^{(g)}) = \left(\int P(Y_{i1}^{(g)} < Y_{i2}^{(g)} | \mu) f_g(\mu) d\mu \right)$ and $P(Y_{i1}^{(g)} > Y_{i2}^{(g)}) = \left(\int P(Y_{i1}^{(g)} > Y_{i2}^{(g)} | \mu) f_g(\mu) d\mu \right)$, respectively. We can easily show that the GOR of responses between periods 2 and 1 for a randomly selected patient i from group g ($= 1, 2$) under model (Eq. 6) is also equal to:^[7,19]

$$\text{GOR}^{(g)} = \frac{\Pi_C^{(g)}}{\Pi_D^{(g)}} = \exp(\eta_{BA} (X_{i2}^{(g)} - X_{i1}^{(g)}) + \gamma (Z_{i2}^{(g)} - Z_{i1}^{(g)})) \quad (8)$$

which is neither a function of the assumed probability density function $f_g(\mu)$ nor a function of the random effects $\mu_i^{(g)}$. On the basis of Eq. 8, we can express the GOR of patient responses for treatment B vs. treatment A (for a fixed period) on a randomly selected patient i as:^[7]

$$\text{GOR}_{BA} = \exp(\eta_{BA}) = \left(\frac{\text{GOR}^{(1)}}{\text{GOR}^{(2)}} \right)^{1/2} \quad (9)$$

Note that $\Pi_C^{(g)}$ and $\Pi_D^{(g)}$ are, by definition, equal to $\sum_{j=1}^{J-1} \sum_{j'=j+1}^J \pi_{jj'}^{(g)}$ and $\sum_{j=2}^J \sum_{j'=1}^{j-1} \pi_{jj'}^{(g)}$, where $\pi_{jj'}^{(g)} = P(Y_{i1}^{(g)} = j, Y_{i2}^{(g)} = j')$, for $j = 1, 2, \dots, J$ and $j' = 1, 2, \dots, J$. As defined previously, we let

$n_{jj}^{(g)}$ denote the number of patients in group g ($= 1, 2$) falling in the cell with the response vector ($Y_{11}^{(g)} = j, Y_{12}^{(g)} = j'$) among n_g patients. We can estimate $\pi_{jj}^{(g)}$ by the sample proportion $\hat{\pi}_{jj}^{(g)} = n_{jj}^{(g)} / n_g$. Thus, we obtain a consistent estimator for $G\hat{O}R^{(g)}$ in group g ($= 1, 2$) as:

$$G\hat{O}R^{(g)} = \frac{\hat{\Pi}_C^{(g)}}{\hat{\Pi}_D^{(g)}} \quad (10)$$

where $\hat{\Pi}_C^{(g)} = \sum_{j=1}^{J-1} \sum_{j'=j+1}^J \hat{\pi}_{jj'}^{(g)}$ and $\hat{\Pi}_D^{(g)} = \sum_{j=2}^J \sum_{j'=1}^{j-1} \hat{\pi}_{jj'}^{(g)}$. This leads us to obtain a consistent estimator for $G\hat{O}R_{BA}$ (Eq. 9) as:

$$G\hat{O}R_{BA} = \left(\frac{G\hat{O}R^{(1)}}{G\hat{O}R^{(2)}} \right)^{1/2} \quad (11)$$

Using the delta method,^[14] we may obtain an estimated asymptotic variance of $\log(G\hat{O}R_{BA})$ as:^[7]

$$\text{Var}(\log(G\hat{O}R_{BA})) = \frac{\sum_{g=1}^2 \left(\frac{\hat{\Pi}_C^{(g)} + \hat{\Pi}_D^{(g)}}{n_g \hat{\Pi}_C^{(g)} \hat{\Pi}_D^{(g)}} \right)}{4} \quad (12)$$

Define $n_{dis}^{(g)} = n_C^{(g)} + n_D^{(g)}$, where $n_C^{(g)} = \sum_{j=1}^{J-1} \sum_{j'=j+1}^J n_{jj'}^{(g)}$ and $n_D^{(g)} = \sum_{j=2}^J \sum_{j'=1}^{j-1} n_{jj'}^{(g)}$ for $g = 1, 2$. We can show that the conditional probability mass function of $n_C^{(1)} = x_1$, given $n_C^{(+)} = n_C^{(1)} + n_C^{(2)}$ fixed, is the noncentral hypergeometric distribution^[14,20,22] given by:

$$P(n_C^{(1)} = x_1 | n_C^{(+)}, n_D^{(1)}, n_D^{(2)}, Q_{BA}) = \frac{\binom{n_D^{(1)}}{x_1} \binom{n_D^{(2)}}{n_C^{(+)} - x_1} Q_{BA}^{x_1}}{\sum_x \binom{n_D^{(1)}}{x} \binom{n_D^{(2)}}{n_C^{(+)} - x} Q_{BA}^x} \quad (13)$$

where $Q_{BA} = (\Pi_C^{(1)} \Pi_D^{(2)}) / (\Pi_D^{(1)} \Pi_C^{(2)}) = G\hat{O}R_{BA}^2$, and the summation for x in the denominator is over the range $\max\{0, n_C^{(+)} - n_D^{(2)}\} \leq x_1 \leq \min\{n_D^{(1)}, n_C^{(+)}\}$.

When $G\hat{O}R_{BA} = 1$ (or $\eta_{BA} = 0$), the noncentral hypergeometric distribution (Eq. 13) reduces to the central hypergeometric distribution:

$$P(n_C^{(1)} = x_1 | n_C^{(+)}, n_D^{(1)}, n_D^{(2)}, Q_{BA} = 1) = \frac{\binom{n_D^{(1)}}{x_1} \binom{n_D^{(2)}}{n_C^{(+)} - x_1}}{\binom{n_D^{(1)} + n_D^{(2)}}{n_C^{(+)}}} \quad (14)$$

where $\max\{0, n_C^{(+)} - n_D^{(2)}\} \leq x_1 \leq \min\{n_D^{(1)}, n_C^{(+)}\}$.

When studying whether there is a difference in effects between treatments A and B, we consider testing $H_0: G\hat{O}R_{BA} = 1$ (or $\eta_{BA} = 0$) vs. $H_a: G\hat{O}R_{BA} \neq 1$ (or $\eta_{BA} \neq 0$). As both $n_C^{(g)}$ and $n_D^{(g)}$ are large, we will reject the null

hypothesis $H_0: G\hat{O}R_{BA} = 1$ on the basis of $G\hat{O}R_{BA}$ (Eq. 11) and $\text{Var}(\log(G\hat{O}R_{BA}))$ (Eq. 12) at the α -level^[7] if:

$$\frac{|\log(G\hat{O}R_{BA})|}{\sqrt{\text{Var}(\log(G\hat{O}R_{BA}))}} > Z_{\alpha/2} \quad (15)$$

where Z_{α} is the upper 100(α)th percentile of the standard normal distribution.

When $n_C^{(g)}$ or $n_D^{(g)}$ is small, we may consider use of Fisher's exact test on the basis of the exact conditional distribution (Eq. 14). We will reject $H_0: G\hat{O}R_{BA} = 1$ at the α -level if we observe $n_C^{(1)} = x_1$ such that:^[7]

$$\min \left\{ P(x \geq x_1 | n_C^{(+)}, n_D^{(1)}, n_D^{(2)}, Q_{BA} = 1), P(x \leq x_1 | n_C^{(+)}, n_D^{(1)}, n_D^{(2)}, Q_{BA} = 1) \right\} \leq \frac{\alpha}{2} \quad (16)$$

where, $P(x \leq x_1 | n_C^{(+)}, n_D^{(1)}, n_D^{(2)}, Q_{BA} = 1) = \sum_{x \geq x_1} P(n_C^{(1)} = x | n_C^{(+)}, n_D^{(1)}, n_D^{(2)}, Q_{BA} = 1)$, and $P(x \geq x_1 | n_C^{(+)}, n_D^{(1)}, n_D^{(2)}, Q_{BA} = 1) = \sum_{x \leq x_1} P(n_C^{(1)} = x | n_C^{(+)}, n_D^{(1)}, n_D^{(2)}, Q_{BA} = 1)$.

Note that the magnitude of a patient change in the ordered category from $j = 1$ (at period 1) to $j = 3$ (at period 2) is larger than that from $j = 1$ (at period 1) to $j = 2$ (at period 2). However, it is not clear whether the magnitude of a patient change from category $j = 1$ (at period 1) to $j = 2$ (at period 2) is equal to that of a patient change from category $j = 2$ (at period 1) to category $j = 3$ (at period 2). When most cell frequencies $n_{jj}^{(g)}$ are reasonably large, we may use the ordinal levels of responses at the first period to form strata and employ a summary test (across strata) with use of Agresti's α accounting for the information on this partial order of patient response changes to improve power.^[8,9] Note that we base posttreatment responses at the first period to form strata, and hence the proposed summary test procedure accounting for the partial order based on Agresti's α can be appropriate only for testing equality of treatments. This is because one can reasonably assume that the patients with the same ordinal level of responses at the first period are comparable between groups under the null hypothesis of equal treatment effects. It can be generally inadequate to do stratified analysis if we use the posttreatment responses to form strata, especially when these patient responses are affected by the treatments in data analysis.

When wishing to produce an interval estimator for $G\hat{O}R_{BA}$, we can obtain an asymptotic 100(1 - α)% confidence interval for $G\hat{O}R_{BA}$ as:^[7]

$$\left[G\hat{O}R_{BA} \exp(-Z_{\alpha/2} \sqrt{\text{Var}(\log(G\hat{O}R_{BA}))}), G\hat{O}R_{BA} \exp(Z_{\alpha/2} \sqrt{\text{Var}(\log(G\hat{O}R_{BA}))}) \right] \quad (17)$$

When $n_C^{(g)}$ or $n_D^{(g)}$ is small, interval estimator (Eq. 17) may lose accuracy. In this case, we may consider use of the

interval estimator on the basis of the exact conditional distribution (Eq. 13). Given $n_C^{(1)} = x_1$, we obtain an exact $100(1 - \alpha)\%$ confidence interval for GOR_{BA} as:^[7]

$$[GOR_{BAL}, GOR_{BAU}] \quad (18)$$

where GOR_{BAL} and GOR_{BAU} are found by solving the following two equations:

$$P(x \geq x_1 | n_C^{(+)}, n_{dis}^{(1)}, n_{dis}^{(2)}, GOR_{BAL}^2) = \frac{\alpha}{2} \text{ and}$$

$$P(x \leq x_1 | n_C^{(+)}, n_{dis}^{(1)}, n_{dis}^{(2)}, GOR_{BAU}^2) = \frac{\alpha}{2}$$

An Example

Consider the crossover trial^[1] that was conducted by 3M-Riker to compare the suitability of two new inhalation devices (A and B) in asthma patients who were using a standard inhaler device delivering Salbutamol. Group 1 used device A for one week followed by device B for another week, while group 2 used these devices in reverse order. No wash-out period was felt necessary. Patients gave their assessment on the clarity of leaflet instructions accompanying the devices on an ordinal scale: “easy,” “only clear after reading,” “not very clear,” and “confusing.” Note that in this example, the higher the ordinal category, the worse is the clarity of the leaflet instruction. When assuming the proportional odds model (Eq. 2) with normal random effects and applying PROC GLIMMIX,^[15] we obtain the MLE and its estimated SE as $\beta_{BA} = -1.283$ and $SE = 0.213$. This gives the p-value < 0.0001 . Thus, there is strong evidence that the clarities of leaflet instructions between devices A and B are different. Furthermore, because $\beta_{BA} < 0$, the leaflet instruction for device B is less clear than that for device A.

When employing test procedures (Eq. 15) and (Eq. 16) to test $H_0: GOR_{BA} = 1$, we obtain both the p-values to be less than 0.001. These results strongly suggest that the clarity of leaflet instruction should be different between devices A and B as well. To estimate the GOR of patient opinions regarding the clarity of leaflet instruction between devices A and B, we obtain $\hat{GOR}_{BA} = 3.637$. This estimate suggests that approximately 3.6 times of the probability that a randomly selected patient felt more unclear of the leaflet instruction for device B than device A vs. that a randomly selected patient felt more unclear of the leaflet instruction for device A than device B. When employing interval estimators (Eq. 17) and (Eq. 18), we obtain 95% confidence intervals to be [2.356, 5.615] and [2.267, 5.891], respectively. Because both the lower limits of these resulting interval estimates fall above 1, there is significant evidence that the clarity of leaflet instructions for device B is worse than that of device A at the 5% level. This finding is again consistent with that found on the basis of the proportional odds model with assuming normal random effects.

THREE-TREATMENT THREE-PERIOD CROSSOVER DESIGN

Suppose that we compare two experimental treatments B and C with a standard treatment (or placebo) A in a three-period crossover design. We let X-Y-Z denote the treatment-receipt sequence of receiving treatments X, Y, and Z at periods 1, 2, and 3, respectively. Say, we randomly assign n_g patients to group g, where $g = 1$ denotes the group with A-B-C treatment-receipt sequence; $g = 2$ denotes the group with A-C-B treatment-receipt sequence; $g = 3$ denotes the group with B-A-C treatment-receipt sequence; $g = 4$ denotes the group with B-C-A treatment-receipt sequence; $g = 5$ denotes the group with C-A-B treatment-receipt sequence; and $g = 6$ denotes the group with C-B-A treatment-receipt sequence. For patient i ($= 1, 2, \dots, n_g$) assigned to group g ($= 1, 2, 3, 4, 5, 6$), we let $Y_{iz}^{(g)}$ denote the ordinal outcome of the patient at period z ($= 1, 2, 3$), and $Y_{iz}^{(g)} = j$ when the patient response falls in the j th ordered category. We let $X_{iz1}^{(g)}$ and $X_{iz2}^{(g)}$ denote the indicator functions of treatment-receipt for treatments B and C, respectively, setting $X_{iz1}^{(g)} = 1$ for the patient receiving treatment B at period z , and $= 0$, otherwise; and $X_{iz2}^{(g)} = 1$ for the patient receiving treatment C at period z , and $= 0$, otherwise. Furthermore, we define $Z_{iz1}^{(g)}$ and $Z_{iz2}^{(g)}$ as the indicator functions for periods 2 and 3.

Normal Random Effects Proportional Odds Model

When using the normal random effects proportional odds model, we can extend model (Eq. 2) to accommodate a three-treatment three-period crossover design by assuming that

$$P(Y_{iz}^{(g)} \leq j | \mu_i^{(g)}) = \frac{\exp(\alpha_j + \beta_{BA} X_{iz1}^{(g)} + \beta_{CA} X_{iz2}^{(g)} + \gamma_{21} Z_{iz1}^{(g)} + \gamma_{31} Z_{iz2}^{(g)} + \mu_i^{(g)})}{1 + \exp(\alpha_j + \beta_{BA} X_{iz1}^{(g)} + \beta_{CA} X_{iz2}^{(g)} + \gamma_{21} Z_{iz1}^{(g)} + \gamma_{31} Z_{iz2}^{(g)} + \mu_i^{(g)})} \quad (19)$$

where $\mu_i^{(g)}$'s denote the random effects due to patients and are assumed to be independent and identically distributed as a normal distribution with mean 0 and unknown variance σ^2 , β_{BA} and β_{CA} denote the relative effects of treatments B and C vs. treatment A, as well as γ_{21} and γ_{31} denote the relative effects of periods 2 and 3 vs. period 1. Note that we can measure the relative effect of treatment C to treatment B by $\beta_{CB} (= \beta_{CA} - \beta_{BA})$. Following similar ideas and arguments as those for equations (3)–(5), we can derive the corresponding likelihood and employ PROC GLIMMIX to obtain the MLEs and confidence intervals, as well as do hypothesis testing based on Wald's or the likelihood ratio test.

Simple Change Score Method

For brevity, we concentrate our discussion on testing equality of treatments B and A. All the following discussions can be similarly done for testing equality of treatments C and A, as well as for testing equality of treatments C and B.

When comparing treatment B with A, we first form strata according to the two periods in which treatments A and B are received. Thus, we form stratum 1 consisting of groups $g = 1$ and 3; stratum 2 consisting of groups $g = 2$ and 4; and stratum 3 consisting of groups $g = 5$ and 6. Within each stratum, we calculate the difference in the base scores between the two periods (in which treatments A and B are received) within patients and reassign patients into the five-point change score scales according to Senn's score scheme. We can then employ a summary trend test, such as a weighted sum of Wilcoxon rank sum tests across strata,^[3,10] based on these resulting five-point change score scales to test equality of treatments A and B.

Distribution-Free Random Effects Model with Using a Conditional Approach

For a given patient i ($= 1, 2, \dots, n_g$) with $\mu_i^{(g)}$ fixed from group g , we assume that the joint probability of $(Y_{iz_1}^{(g)}, Y_{iz_2}^{(g)})$, where z_1 & $z_2 = 1, 2, 3$ and $z_1 < z_2$, satisfies:^[8,19]

$$P(Y_{iz_1}^{(g)} < Y_{iz_2}^{(g)} | \mu_i^{(g)}) = \frac{1}{1 + \exp(\mu_i^{(g)} + \eta_{BA} X_{iz_1 1}^{(g)} + \eta_{CA} X_{iz_1 2}^{(g)} + \gamma_{21} Z_{iz_1 1}^{(g)} + \gamma_{31} Z_{iz_1 2}^{(g)})} \times \frac{\exp(\mu_i^{(g)} + \eta_{BA} X_{iz_2 1}^{(g)} + \eta_{CA} X_{iz_2 2}^{(g)} + \gamma_{21} Z_{iz_2 1}^{(g)} + \gamma_{31} Z_{iz_2 2}^{(g)})}{1 + \exp(\mu_i^{(g)} + \eta_{BA} X_{iz_2 1}^{(g)} + \eta_{CA} X_{iz_2 2}^{(g)} + \gamma_{21} Z_{iz_2 1}^{(g)} + \gamma_{31} Z_{iz_2 2}^{(g)})}$$

$$P(Y_{iz_1}^{(g)} > Y_{iz_2}^{(g)} | \mu_i^{(g)}) = \frac{1}{1 + \exp(\mu_i^{(g)} + \eta_{BA} X_{iz_2 1}^{(g)} + \eta_{CA} X_{iz_2 2}^{(g)} + \gamma_{21} Z_{iz_2 1}^{(g)} + \gamma_{31} Z_{iz_2 2}^{(g)})} \times \frac{\exp(\mu_i^{(g)} + \eta_{BA} X_{iz_1 1}^{(g)} + \eta_{CA} X_{iz_1 2}^{(g)} + \gamma_{21} Z_{iz_1 1}^{(g)} + \gamma_{31} Z_{iz_1 2}^{(g)})}{1 + \exp(\mu_i^{(g)} + \eta_{BA} X_{iz_1 1}^{(g)} + \eta_{CA} X_{iz_1 2}^{(g)} + \gamma_{21} Z_{iz_1 1}^{(g)} + \gamma_{31} Z_{iz_1 2}^{(g)})}$$

and

$$P(Y_{iz_1}^{(g)} = Y_{iz_2}^{(g)} | \mu_i^{(g)}) = 1 - P(Y_{iz_1}^{(g)} > Y_{iz_2}^{(g)} | \mu_i^{(g)}) - P(Y_{iz_1}^{(g)} < Y_{iz_2}^{(g)} | \mu_i^{(g)}) \quad (20)$$

where η_{BA} and η_{CA} denote the respective effect of treatments B and C relative to treatment A, as well as γ_{21} and γ_{31} denote the respective effect of periods 2 and 3 vs. period 1. The GORs of responses for treatment B vs. treatment A and for treatment C vs. treatment A are defined as $\text{GOR}_{BA} = \exp(\eta_{BA})$ and $\text{GOR}_{CA} = \exp(\eta_{CA})$, respectively. The GOR of responses for treatment C vs. treatment B is equal to $\text{GOR}_{CB} = \exp(\eta_{CA} - \eta_{BA})$. For brevity, we discuss only GOR_{BA} in the following. The discussion on hypothesis testing and interval estimation for GOR_{CA} and GOR_{CB} can be done similarly.

We define $n_C^{(g)}(z_1, z_2)$ as the number of patients with their responses at period z_1 lower than those at period z_2 among

n_g patients in group g . Similarly, we define $n_D^{(g)}(z_1, z_2)$ as the number of patients with their responses at period z_1 higher than those at period z_2 among n_g patients in group g . We define the vector of frequencies $(f_{11k}, f_{12k}, f_{21k}, f_{22k})$ in a 2×2 table for table $k = 1, 2, 3$ as:

$$\begin{aligned} (f_{111} = n_C^{(1)}(1, 2), f_{121} = n_D^{(3)}(1, 2), \\ f_{211} = n_D^{(1)}(1, 2), f_{221} = n_D^{(3)}(1, 2)), \\ (f_{112} = n_C^{(2)}(1, 3), f_{122} = n_C^{(4)}(1, 3), \\ f_{212} = n_D^{(2)}(1, 3), f_{222} = n_D^{(4)}(1, 3)), \\ \text{and } (f_{113} = n_C^{(5)}(2, 3), f_{123} = n_C^{(6)}(2, 3), \\ f_{213} = n_D^{(5)}(2, 3), f_{223} = n_D^{(6)}(2, 3)) \end{aligned} \quad (21)$$

We can show that the underlying common odds ratio (OR) of the three 2×2 tables defined in Eq. 21 is equal to $\text{GOR}_{BA}^{2, [8,19]}$. Thus, one can employ all statistical methods^[14,21] developed for a series of 2×2 tables to study the relative treatment effect GOR_{BA} . For example, consider testing $H_0: \text{GOR}_{BA} = 1$ vs. $H_a: \text{GOR}_{BA} \neq 1$ we may use the weighted-least-squares (WLS) summary test procedure.^[23] We will reject $H_0: \text{GOR}_{BA} = 1$ at the α -level^[8] if:

$$\left(\frac{\sum_{k=1}^3 W_k \text{LGOR}_{BA}^{(k)}}{\sum_{k=1}^3 W_k} \right)^2 \left(\sum_{k=1}^3 W_k \right) > Z_{\alpha/2}^2 \quad (22)$$

where $W_k = 4 / (1/f_{11k} + 1/f_{12k} + 1/f_{21k} + 1/f_{22k})$ and $\text{LGOR}_{BA}^{(k)} = \log((f_{11k} f_{22k}) / (f_{12k} f_{21k}))^{1/2}$, and Z_{α} is the upper 100(α)th percentile of the standard normal distribution. Note that if $f_{ijk} = 0$ for some observed frequencies in a 2×2 table k , we cannot calculate the test statistic (Eq. 22). We may apply the commonly used ad hoc arbitrary adjustment procedure for sparse data by adding 0.50 to each observed frequency f_{ijk} in this particular table k . We may also consider use of the Mantel-Haenszel (MH) summary test procedure^[14,19,24] for testing non-equality of treatments when one fails to employ the test procedure (Eq. 22) due to $f_{ijk} = 0$ for some cells.^[8]

When $n_C^{(g)}(z_1, z_2)$ and $n_D^{(g)}(z_1, z_2)$ are small, both the WLS and MH test procedures are theoretically invalid. In this case, we may consider use of the test procedure based on the exact conditional distribution. Given $f_{11+}^0 (= f_{111}^0 + f_{112}^0 + f_{113}^0)$, we will reject $H_0: \text{GOR}_{BA} = 1$ at the α -level^[8] if:

$$\min \left\{ P(f_{11+} \leq f_{11+}^0 | f_{+1}, f_{+2}, f_{-1}, f_{-2}), \right. \\ \left. P(f_{11+} \geq f_{11+}^0 | f_{+1}, f_{+2}, f_{-1}, f_{-2}) \right\} \leq \frac{\alpha}{2}$$

where $P(f_{11+} \leq f_{11+}^0 | f_{+1}, f_{+2}, f_{-1}, f_{-2})$

$$= \sum_{f_{11+} \leq f_{11+}^0} \prod_{k=1}^3 \frac{\binom{f_{+1k}}{f_{11k}} \binom{f_{+2k}}{f_{1+k} - f_{11k}}}{\binom{f_{++k}}{f_{1+k}}}$$

$$\text{and } P(f_{1+} \geq f_{1+}^0 \mid \underline{f}_{+1}, \underline{f}_{+2}, \underline{f}_{+1+}, \underline{f}_{+2+})$$

$$= \sum_{i_{1+} \geq f_{1+}^0} \prod_{k=1}^3 \frac{\binom{f_{+1k}}{f_{1+k}} \binom{f_{+2k}}{f_{1+k} - f_{1+k}}}{\binom{f_{+k}}{f_{1+k}}} \quad (23)$$

where $a_k \leq f_{1+k} \leq b_k$, $a_k = \max\{0, f_{1+k} - f_{+2k}\}$, $b_k = \min\{f_{+1k}, f_{1+k}\}$ (for $k = 1, 2, 3$), as well as $\underline{f}_{-u+} = (f_{u+1}, f_{u+2}, f_{u+3})'$ for $u = 1, 2$, and $\underline{f}_{-v+} = (f_{+v1}, f_{+v2}, f_{+v3})'$ for $v = 1, 2$.

Also, we can derive asymptotic interval estimators for GOR_{BA} based on WLS and MH method.^[8] Furthermore, because the underlying common OR of the three 2×2 tables (Eq. 21) is equal to GOR_{BA}^2 , we may derive the exact confidence interval for the underlying OR^[14,19,21] based on the product of the noncentral hypergeometric distributions across strata. We then take the square root of these confidence limits to obtain the exact confidence interval for GOR_{BA} .^[8]

An Example

Consider the crossover trial^[25] comparing an analgesic at low (L) and high (H) doses with a placebo (P) for relief of pain in primary dysmenorrhea patients. Here, we regard placebo as treatment A, as well as the low and high doses as treatments B and C. There were 86 patients randomly assigned to one of six groups distinguished by treatment-receipt sequences: P-L-H ($g = 1$), P-H-L ($g = 2$), L-P-H ($g = 3$), L-H-P ($g = 4$), H-P-L ($g = 5$), and H-L-P ($g = 6$). At the end of each treatment period, each patient was assessed the extent of relief on the ordinal scale: none, moderate, and complete. We code these as 1, 2, and 3, respectively. When employing PROC GLIMMIX, we obtain the MLEs (and their estimated SEs) as $\hat{\beta}_{\text{BA}} = -2.041$ (SE = 0.327), $\hat{\beta}_{\text{CA}} = -2.416$ (SE = 0.333), and $\hat{\beta}_{\text{CB}} = -0.374$ (SE = 0.284). On the basis of these estimates (of which the signs are all < 0), we may conclude that both the low and high doses can significantly improve, as compared with the placebo, the relief extent of pain at the 5% level. We also note that although the high dose can improve the outcome of patients using the low dose, this improvement is not significant at the 5% level.

When applying the WLS procedure (Eq. 22) and the exact testing procedure (Eq. 23) to test $H_0: \text{GOR}_{\text{BA}} = 1$ (or $H_0: \eta_{\text{BA}} = 0$), as well as the corresponding procedures to test $H_0: \text{GOR}_{\text{CA}} = 1$ (or $H_0: \eta_{\text{CA}} = 0$), we obtain all p-values < 0.0001 .^[8] These suggest that either the low or high dose of the analgesic vs. the placebo can affect the relief of pain in primary dysmenorrhea. When studying the relative effect of high dose vs. the low dose on the relief extent of pain, we apply the WLS and the exact procedure to test $H_0: \text{GOR}_{\text{CB}} = 1$. We obtain p-values as 0.433 and 0.649, respectively. Thus, there is no significant evidence that we have a difference in the relief extent of pain between the high and low doses. The results and other estimations for the GOR appear elsewhere.^[8,19]

INCOMPLETE BLOCK CROSSEVER DESIGN

When employing a crossover design to compare three or more treatments, the duration of a crossover trial, in which every patient receives each of the treatments under comparison, can be much longer than that of a parallel groups design. This can cause difficulty in recruiting patients into a trial and the burden of ensuring patients to follow the protocol closely. To alleviate these concerns, we may consider employing an incomplete block design in which each patient is to receive only a subset of treatments rather than all treatments under comparison.^[3,26] When using the normal random effects proportional odds model (Eq. 19) excluding the term containing γ_{31} for period 3 vs. period 1, we can still apply PROC GLIMMIX to do hypothesis testing and interval estimators for the relative treatment effect without any extra effort. Using the same set of strata as defined in the previous section, for example, we can easily derive a summary test based on the simple change score method for testing equality of treatments A and B. We can also use similar ideas as those suggested elsewhere^[27,28] and modify test procedures and interval estimators in binary data to accommodate the situations in which the patient responses are in ordinal data under the incomplete block design when using the GOR to measure the relative treatment effect.

FOUR-TREATMENT FOUR-PERIOD CROSSEVER DESIGN

When we employ the crossover design to compare four or more treatments, the number of groups with different treatment-receipt sequences can be too large to be of use. For example, when comparing four treatments over a four-period crossover design, there are 24 ($=4!$) groups with different treatment-receipt sequences. In this case, we may employ a Latin square^[3] to reduce the number of groups with different treatment-receipt sequences. It is straightforward to extend the model (Eq. 19) by including more indicator functions of treatment-received covariates and periods to accounting for a four-treatment four-period crossover design and apply PROC GLIMMIX despite of using a Latin square. Also, all the results based on the WLS method, the MH approach, and the exact conditional distribution can be, as shown elsewhere,^[8] modified to accommodate a four-treatment four-period crossover design under a 4×4 Latin square.

CONCLUSION

We need to assume the random effects in the model (Eq. 1) [or model (Eq. 19)] to be normal in use of PROC GLIMMIX to obtain the MLEs, but the normal random effects proportional odds model is ready to use for various

crossover designs. The parameters in this model are meaningful and easily understood. These parameters can also provide a summary measure to quantify the relative treatment effect. Furthermore, when the normal random effects proportional odds model assumptions are satisfied, the model-based test procedures and estimators are more efficient than the other approaches. When the number of patients in a trial is small, however, the MLEs and their relevant test procedures can be invalid in sparse data.^[29] By contrast, use of the simple change score method does not need to assume a parametric model for the underlying data and the calculation of this method is tractable. Also, since the change score method collapses ordinal data into a few categories, the use of change score test procedure can be subject to less concern of sparse data than Wald's or the likelihood tests. However, reassigning patients according to the difference in the base scores to categories on a change score scale seems to be arbitrary. It can also be difficult to provide an easily interpreted summary measure of the relative treatment effect based on the change score method. Using the GOR to measure the relative treatment effect and the conditional approach, we can avoid assuming normality for random effects. The GOR of responses can be easily appreciated and interpreted. We can derive the exact test procedure and interval estimator for the GOR in small sample cases. Furthermore, all asymptotic test procedures and estimators based on the conditional approach can be expressed in closed forms and be calculated by a hand calculator. Since it excludes the information on patients with identical levels of responses between periods, however, the use of the conditional approach with the GOR can lose efficiency. Finally, we note that test procedures and estimators using the above three approaches can all be easily modified to study the period effect.

Parallel Design

Mani Y. Lakshminarayanan

Biostatistics and Research Decision Sciences, Merck & Co, Inc., Rahway, New Jersey, U.S.A.

Abstract

Parallel design is probably the simplest and the most commonly used design employed in clinical trials for evaluation of the effectiveness and safety of an experimental drug against a control. This entry describes the basic principles of parallel design and provides multiple examples of various types of parallel design.

Keywords: Analysis of covariance; Endpoints; Multi-center trials; Multiple comparisons; Protocols; Randomized block design; Sample size.

INTRODUCTION

Statisticians involved in clinical research in the pharmaceutical industry encounter design of experiments almost on a daily basis while writing protocols for their clinical studies. At the outset, the primary objective(s) described in the protocols involve comparing different dose groups; to accomplish this, patients are assigned randomly to the dose groups. This general idea of assigning patients to different groups is similar to those agricultural experiments conducted by Sir Ronald Fisher, who is considered to be the father of many fundamental statistical concepts, including design of experiments, at the Rothamsted Agricultural Experiment Station near London. Sir Austin Bradford Hill was primarily instrumental in the development of controlled clinical trials in Britain. His publications in the early 1950s^[1] included fundamental concepts such as random allocation, concurrent controls, eligibility of patients, treatment schedule, and statistical analysis of the clinical data.

OVERVIEW

The term *experimental design* comes from these agricultural experiments, where the experimenters sow varieties in or apply treatments to plots, and often these plots were arranged in blocks. At this time, readers are asked to take note of terms like *randomly* and *blocks*. Variations of these experiments are carried out in clinical trials when patients are randomly allocated across various treatments within each investigational site, also known as a *center*. These basic ideas will be discussed further in this entry.

As an example, imagine a clinical trial that is planned to compare the effectiveness of an experimental drug against placebo in the treatment of patients with schizophrenia, or schizoaffective disorder. In order to accomplish

the primary objective, it is decided to include more than one dose of the experimental drug. As we think about this clinical trial, a number of important questions arise:

1. Are these dose groups different in efficacy?
2. Are there other characteristics of the patients that might affect the efficacy that should be controlled or investigated?
3. How many patients should be assigned to each dose group?
4. How should the patients be assigned to each dose group, and how the data should be collected?
5. What analysis method should be used on the collected data?
6. If there are differences between the dose groups, which ones are different?

It is important to answer all of these questions before concluding that a given trial is positive or not. Some of these issues will have to be specified a priori in the protocol, as required by the International Conference on Harmonization (ICH) Guidelines (ICH E-9);^[2] readers are referred to the entry titled *Protocol Development* for more details on the protocol specification.

Although the final conclusions in any clinical trial may depend largely on the conduct of the trial itself, it is absolutely crucial that the protocol team (including clinicians and statisticians) spend enough time on the design part of the trial. This entry is intended to discuss one of the commonly used designs in clinical trials.

DEFINITION

The simplest and the most commonly used designs employed in clinical trials are *parallel designs*. In a trial

with parallel designs, a patient is assigned randomly to one and only one treatment, as opposed to crossover designs, in which the same patient is given two or more treatments within a trial. Differences between these two types of designs will not be discussed further in this entry.

In parallel designs, there are usually at least two treatment groups: experimental and control. In our earlier example of a study involving schizophrenia, there are several dose groups of the experimental drug and a placebo as the concurrent control. Controls in clinical trials are used as standard treatments to compare and to evaluate the effectiveness of an experimental drug. When there are no standard marketed treatments available, and if it is ethical, then placebo controls are used as standard comparators. If a standard therapy is available (e.g., anti-infectives or antihypertensives), then it may be required to use it as a control to evaluate quantitatively the efficacy and safety of an experimental drug; thus a relative risk-benefit can be specified. The importance of proper controls as a part of well-designed clinical trials is stressed in ICH Guidelines (ICH E-9), especially in their requirements for sponsors to provide at least two well-controlled trials as pivotal for the new drug approvals (NDAs). There are other types of control, such as no control and historical control, that are used less frequently in clinical trials.

It is noted in this simplest definition of parallel designs, where we simply assign patients to one and only one treatment, that no specific patient characteristics that may have a bearing on the response are taken into consideration. These patient characteristics or other trial-related characteristics are typically known as *prognostic variables*. Designs that incorporate these prognostic variables (e.g., randomized block designs, analysis of covariance) will be discussed later in this entry.

THREE BASIC CONCEPTS IN EXPERIMENTAL DESIGNS

The three basic principles that serve as keystones to the development of experimental designs are: *randomization*, *replication*, and *blocking*.

There is enough literature discussing the need for using randomization in clinical trials before treatments can be compared, but there are also references in the literature that argue against the use of randomization. It was the work of pioneers such as Sir R.A. Fisher that influenced the use of randomization as the cornerstone application of statistical theory in experimental design. A classic paper by Peto et al.^[3] presents a convincing argument for using randomization in clinical trials.

In a trial with multiple doses of the experimental drug and a placebo (such as the trial described in the previous section on patients with schizophrenia), patients are assigned to each group at random using a predetermined scheme. These randomization schemes can always be

generated using computer algorithms. In general, there are several benefits associated with using random assignment of patients to treatments: avoidance of any bias in the results, balancing of prognostic factors, ensurance of proper conduct of trials, and validation of assumptions needed to apply certain statistical techniques.

The use of *replication*, as emphasized by Fisher, is critical to reduce variability or to get a proper estimate of the error variance. In general, *replication* means repetition of an entire experiment, or portions thereof, under similar experimental conditions. Although similar experimental conditions are desirable, it is not useful to obtain identical analytical results. To accomplish this, experiments can be repeated under two or more sets of conditions, for example, within a time window that is considered in a trial. For example, analysis of clinical trials data where measurements are collected across time points (e.g., blood pressure measurements in trials involving patients with hypertension) involves “change from baseline to final time point” as the response variable. In this case, a time window can be created for both baseline and final time point so that measurements can be repeated during the time window (e.g., three blood pressure measurements can be taken both at baseline and at final). Replicated measurements allow the experimenter to estimate accurately the experimental error or to estimate precisely the error variance if a sample mean is used in the estimation of a factor effect.

Blocking is used as a technique for increasing the precision of an experiment. A *block* is a subset of experimental units that are more homogeneous than the entire experiment itself. For example, in many clinical trials, responses to treatments are different for various groups of patients based on their age, sex, race, or initial severity of disease, which are some commonly cited prognostic variables that may have an impact on the response. Blocking (also known as *matching* in some literature) is a technique used to control the variability of the response caused by these prognostic variables. Randomized block designs are used to take blocks into account in the design. An example of a randomized block design is a paired comparison design, in which two patients who have similar characteristics are paired and the two treatments (drug and placebo in a two-group trial) are assigned to each member of the pair.

A sensible alternative to blocking as a method to control for the prognostic variables is *stratification*. A common stratification variable is center. Other prognostic variables, such as age, sex, race, and initial severity, can also be considered as stratification variables. For example, age could be grouped into, say, $\text{age} < 18$, $18 \leq \text{age} \leq 64$, and $\text{age} \geq 65$ as different strata. With this definition of strata for age, it is noted that patients who are homogeneous based on their age category are grouped. With regard to randomization, patients would then be randomized within each stratum separately. In clinical trials, it is very common to produce

an independent set of randomization schedules for each investigational center.

Blocking and stratification are quite often used within the same data. For example, within each stratum, randomizations could be carried out using simple random samples, or blocking could be used in the randomizations. Thus, blocked randomization is a special kind of stratification. The smallest block size is the sum of the integers defined by the allocation ratio (for a 1:1 allocation, block size is 2). Use of a large number of strata may increase the chance of departure from the specified allocation ratio, unless small block sizes are used within each stratum.

EXAMPLES OF PARALLEL DESIGNS

Completely Randomized Design

The simplest version of a completely randomized design is a one-way classification model, which is a single-factor experiment with two or more levels of a design factor, such as clinical trial designed to compare several doses of an experimental drug and a placebo where all patient data are obtained from one clinic or hospital. Mathematically, this model can be written as

$$y_{ij} = \mu_i + \varepsilon_{ij} \begin{cases} i = 1, 2, \dots, a \\ j = 1, 2, \dots, n_i \end{cases} \quad (1)$$

where y_{ij} is the (ij) th observation, a is the number of treatments (number of doses and placebo), and n_i is the number of observations in the i th treatment.

For the underlying model presented in Eq. 1, our interest is to test for the equality of the treatment means; that

is, $H_0: \mu_1 = \mu_2 = \dots = \mu_a$ If the null hypothesis is true, then it is well known that the ratio $F = MSA/MSE$ is distributed as F with $(a - 1)$ and $(N - a)$ degrees of freedom. Definitions of the terms used are as follows:

$$MSA = \frac{SSA}{a - 1} \quad MSE = \frac{SSE}{N - a} \quad (2)$$

$$SSA = \sum_i n_i (\bar{y}_i - \bar{y}_{..})^2 \quad SSE = \sum_i \sum_j (y_{ij} - \bar{y}_i)^2$$

$$N = \sum_i n_i \bar{y}_i = \sum_j \frac{y_{ij}}{n_i} \bar{y}_{..} = \sum_i \sum_j \frac{y_{ij}}{N}$$

Although these mathematical formulations would guide us in determining whether there is any signal for a difference between the treatment means, a similar analysis in clinical trials would be considered incomplete until the next step is taken, viz., responding to the primary objective specified in the protocol of showing whether or not the experimental therapy is efficacious. In other words, it is important for us to know which treatments differ from what and the

magnitude of those differences. In order to answer this primary objective in a protocol, the statistical analysis will have to involve the method of *multiple comparisons*, which will be briefly described at the end of this entry and will be covered in detail in another entry.

Designs with Prognostic Factors

One of the most widely used designs for controlling known sources of variability due to the prognostic factors is a *randomized block design*. In the case of a large phase II/III clinical trial, the study team may be required to carry out this trial across several investigational centers. Studies like this are known as *multicenter trials*. Some of the important reasons and rationale for conducting a multicenter trial include the ability to generalize the results across different set of patients and treatment settings, and expediting the enrollment of patients in a large trial. If center is considered as a stratification variable, then individual randomizations are carried out within each center. A balanced treatment assignment within each center is generally desired.

With treatment and center (as a blocking variable) in a randomized block design with complete blocks (that is, one observation per treatment in each center), the statistical model can be written as

$$y_{ij} = \mu_i + \beta_j + \varepsilon_{ij} \begin{cases} i = 1, 2, \dots, a \\ j = 1, 2, \dots, b \end{cases} \quad (3)$$

The model presented in Eq. 3 has no term included for a possible interaction between the treatments and centers. An interaction between treatment and center may exist if the directions of the treatment difference are different across centers. Because most of the analysis in a multicenter trial is based on pooled data from various centers, guidelines from most regulatory agencies suggest that a preliminary test for the treatment by center be carried out (ICH E-9 Guidelines). Thus, it is almost standard practice to consider the following revised model to Eq. 2:

$$y_{ij} = \mu_i + \beta_j + \mu\beta_{ij} + \varepsilon_{ij} \begin{cases} i = 1, 2, \dots, a \\ j = 1, 2, \dots, b \end{cases} \quad (4)$$

The interaction model in Eq. 4 is also popularly known as *cell means model*.

Hypotheses involving the equality of treatment means (μ_i), center means (β_j), and existence of interaction ($\mu\beta_{ij}$) can be tested using various sums of squares terms, similar to the ones shown in Eq. 2, once the analysis of variance table is set up.^[4] It is common to test for the interaction first. If this test is nonsignificant, it is often taken to be a sufficient (but not necessary) justification for pooling data across centers and for concluding that the treatment differences are sufficiently consistent. If a significant interaction

is identified, it is expected that the sources of the interaction, such as dropout rates and eligibility criteria, are explored and explained in the final analysis. Although it is partly based on one's judgment and what is prespecified in the statistical analysis plan in the protocol, the primary hypothesis is usually based on the two main-effects terms.

The *analysis of covariance* is another design that can be used to control the effects of prognostic variables. Imagine an experiment with a response variable y and with another variable x , where y is linearly related to x . Further, x cannot be controlled but can be observed along with y . The variable x is called a *covariate* or a *concomitant* variable. As indicated in the previous section "Three Basic Concepts in Experimental Designs," some examples of covariates are demographic variables such as age, sex, race, and baseline severity of the disease. The use of covariates is restricted to quantitative variables, and it is purely a statistical method for controlling the effects of prognostic variables; no special effort is needed for any prestudy arrangements such as randomization.

For a completely randomized design with a single factor (e.g., treatments) and a covariate (e.g., baseline severity), a statistical model can be written as

$$y_{ij} = \mu + \tau_i + \beta_i(x_{ij} - \bar{x}_{..}) + \varepsilon_{ij} \quad \left\{ \begin{array}{l} i = 1, 2, \dots, a \\ j = 1, 2, \dots, n_i \end{array} \right. \quad (5)$$

Note that the model in Eq. 5 assumes that the regression lines (number = a) have the same slope; that is, the regression lines are parallel. If the regression lines are not parallel, it is reasonable to expect an interaction between the treatments and the covariate. In order to accommodate this, the model in Eq. 5 can be generalized as

$$y_{ij} = \mu + \tau_i + \beta_i(x_{ij} - \bar{x}_{..}) + \varepsilon_{ij} \quad \left\{ \begin{array}{l} i = 1, 2, \dots, a \\ j = 1, 2, \dots, n_i \end{array} \right. \quad (6)$$

For the models specified in Eqs. 5 and 6, analyses for testing various hypotheses can be carried out using the classical ANOVA procedure. A general regression approach can also be developed for this purpose.^[4,5]

Note that in the models referred to so far, an intrinsic assumption is made that the response is measured at one time point, which is not a reality in most clinical trials. Most clinical trials involve measuring responses from a patient across several time periods (e.g., blood pressure measurements taken at several time points in a hypertension trial). Although there are repeated measurements made on subjects, one of the models already explained is used at each time point as a standard analysis. A most widely used time point is the last observation carried forward (LOCF), with the response considered as the change from baseline to this time point.

In repeated-measurements designs, there are two sizes of experimental units, subject and subject's time. Thus,

there are two parts in the model and the analysis, comparison of treatments based on subject's response and comparison of time and treatment by time interaction. Although the structure and the model considered when there are repeated measurements are similar to those of a split-plot design, the two designs operate under different assumptions. One of the main differences is that the subjects are randomly assigned to the levels of treatment, but the time intervals are not. The experimental design used for this type of data is known as *repeated-measures design*. For the analysis of such a design, one can use either a classical ANOVA approach or a multivariate approach.^[4]

ANALYSIS ISSUES

Baseline Information

Measurements are often collected longitudinally in parallel group designs in order to study the time effect and long-term safety data. In such cases, baseline measurements can be considered as valuable covariates in determining the treatment effect. Comparison of treatments are typically studied in terms of mean change from baseline using an Analysis of Covariance (ANCOVA) model with baseline value as a covariate and either the post-baseline value or the calculated change from baseline value as the dependent variable. Estimates and inference based on an ANCOVA model conditional on baseline measurements are unbiased under normality assumption in Ref. [6]. When the baseline measurement is correlated with measurements that are observed post-baseline, any adjustment made for baseline using ANCOVA has been shown to remove the conditional bias in treatment group comparisons due to chance imbalances and to improve efficiency over unadjusted comparisons in Ref. [7].

When several post-randomization measurements (repeated measures over time) are collected in a trial, a longitudinal data analysis (LDA) model can be used. In such a model, the change from baseline is calculated at each post-randomization time point and the baseline measurement is included as a covariate in the model. This model is referred to as the longitudinal ANCOVA model. An alternative approach, a full likelihood approach, initially proposed by Liang and Zeger^[8] can also be suggested in this scenario. This full likelihood LDA model includes baseline values as dependent variable in the response vector along with the post-baseline values. It is worth pointing out that the baseline mean responses for each treatment group are implicitly assumed equal in the longitudinal ANCOVA model and this assumption is a reasonable one due to randomization. A similar "constraint" can also be imposed in the full likelihood LDA model, which can be called as the constrained full likelihood LDA model (cLDA).

There are several advantages of the constrained LDA model over the longitudinal ANCOVA model: it provides

more efficient between group comparison with unbiased standard errors for within-group treatment effects, coverage at the appropriate $100(1 - \alpha)\%$ level under normality, includes baseline measurements of subjects who have missing post-baseline measurements, provides flexibility for stratification and does not make restrictive assumption regarding correlation between baseline and post-baseline measurements.

When SAS PROC MIXED procedure is used to fit a longitudinal ANCOVA model with repeated measures and missing data, the default LSMEANS estimates may not be appropriate. To fix this problem, the baseline mean should be calculated outside the SAS PROC MIXED procedure, using one baseline observation per subject. This calculated mean can be used in the LSMEANS statement with the AT= option or in the ESTIMATE statement. When the model is more complicated (e.g., adjustment for other factors), then the ESTIMATE statement provides more flexibility.

Multiple Comparison

In the “Completely Randomized Design” section, while discussing the test of significance for the equality of treatment means, it was indicated that a significant overall F -test would signal a difference in treatment means. In most clinical trials, showing the existence of an overall experimental effect is of little interest to the primary objective. In a trial involving several doses of an experimental drug and a placebo, one’s primary interest is to see how many doses are different from placebo, i.e., pairwise comparisons between placebo and all doses. Methods that are used to find these pairwise differences are known as *multiple comparisons*. Multiple comparison procedures are employed with a primary goal of controlling either a family-wise error rate (FWER) or more recently false discovery rate (FDR). Preference of choosing FDR over FWER for controlling multiplicity depends on the experimental hypotheses. A great number of procedures are available in the literature in this regard. A detailed discussion of these methods and their rationale will be covered in another entry.

Multiple Time Points

As discussed in “Designs with Prognostic Factors,” if we repeatedly measure patient’s responses across various time points and perform an analysis at each time point, then it can create a multiplicity issue. A repeated-measures design with follow-up multiple comparisons^[4] can be used to handle this issue. As explained in the previous section, a common and effective method of handling multiple time points is to express the repeated data in terms of a single time point, for example, LOCF time point. This time point is often considered the primary time point for analyses of the primary endpoints. Other useful approaches include using the slope for each patient across time or the area under the curve (AUC) as primary endpoints. Diggle et al.^[9] discuss

other approaches that are useful for analyzing data with repeated measures some of which have described in the section “Baseline Information” above.

Multiple Endpoints

It is very common that more than one endpoint (measurement) is specified as primary in phase II/III protocols. For example, in trials designed to study the efficacy and safety of an antipsychotic drug on patients with schizophrenia, one or more derived measurements from the Positive and Negative Symptoms Scale (PANSS) and the Clinical Global Assessment scales are considered primary. For these different endpoints, a separate analysis is carried out and p -values are reported separately. A problem with this type of approach is when to declare the drug efficacious. For instance, if there are five primary endpoints and only three of them show statistical significance, can we still claim efficacy? To avoid this, some protocols tend to specify only one endpoint as primary and the rest as secondary. In the analysis section, an attempt will then be made to explore the consistency of various results. Other scenarios include: declaring a set of primary endpoints as “co-primary endpoints,” multiple primary endpoints in multiple treatment arms, and clinically ordered primary endpoints. In the case of “co-primary endpoints,” no adjustment for multiple endpoints is necessary as it can be shown that the overall FWER is at most equal to the nominal α -level; see Sankoh, D’Agostino and Huque^[10] for more discussion on co-primary endpoints and some general strategies for dealing with multiple co-primary endpoints.

One approach is to consider a composite measure that can be constructed based on the primary endpoints.^[11] Although p -values are derivable for these composite measures, they are not as easy to interpret as changes or percentage changes. Multivariate approaches provide alternatives for handling multiple endpoints.

Combination Treatments

Combination treatments are very common in cancer trials. Traditionally, for combination therapies, a Phase I trial for toxicity and a separate Phase II trial for efficacy are conducted. Huang et al.^[12] have proposed a method of integrating these two phases into one. Their approach involve using a Phase I/II clinical trial to evaluate simultaneously the safety and efficacy of combination dose levels, and then select the optimal combination dose. The underlying approach involves using Bayesian posterior probabilities in the randomization to adaptively assign more patients to doses with higher efficacy levels. Combination doses with lower efficacy are temporarily closed and those with intolerable toxicity are eliminated from the trial. The trial is stopped if the posterior probability for safety, efficacy, or futility crosses a prespecified boundary.

Sample Size

If there are two groups in the design, then sample size determination is straightforward. For normally distributed variables with a common variance σ^2 , the sample size formula for each treatment group is given as $n = 2\sigma^2(z_{\alpha/2} + z_\beta)^2/(\mu_1 - \mu_2)^2$ where μ_1 and μ_2 are the true means, probability of type I error is α , and the power of the test is $1 - \beta$.

The determination of sample sizes for clinical studies with several groups (more than two) involves critical values from a *noncentral F-distribution*.^[13,14] Statisticians faced with this problem in clinical trials tend to use a practical solution; viz., they convert this into a two-group problem, where the groups chosen have the smallest difference. For this smallest difference ($\mu_1 - \mu_2$), the sample size is chosen and is considered for the entire protocol. Other issues, such as adjusting the significance level for multiple comparisons and dose-response designs, are also considered for determining sample size.

CONCLUSION

Parallel design is probably the simplest and the most commonly used design employed in clinical trials for evaluation of the effectiveness and safety of an experimental drug against a control (e.g., a placebo control or an active control). It is suggested that statistical analysis be performed in compliance with statistical principles as specified in the ICH E-9 guideline for good clinical practice.

Patient Compliance

Kenneth B. Schechtman

Washington University School of Medicine, St. Louis, Missouri, U.S.A.

Abstract

Poor compliance to prescribed medication is a common problem that can have a major impact on the success of routine patient care and on the conduct and conclusions of clinical trials. The focus of this entry is on compliance to medication regimens and ways in which to measure the effect of non-compliance on a clinical trial.

INTRODUCTION

Poor compliance to prescribed medication is a common problem that can have a major impact on the success of routine patient care and on the conduct and conclusions of clinical trials. Reported clinical correlates of poor compliance include increased hospitalization in patients with hypertension,^[1] diminished improvements in low-density lipoprotein cholesterol levels in hypercholesteremic patients,^[2] and increased mortality in patients with acute myocardial infarction.^[3] The potential effects of inadequate compliance in clinical trials include underestimation of true therapeutic efficacy because medication is not taken as intended and large increases in sample-size requirements because between-group differences are reduced.^[4–7] If the therapeutic impact of poor compliance is of sufficient magnitude, the associated reduction in statistical power can produce negative conclusions in a study that might otherwise have been positive.

Broadly speaking, if a patient's behavior is consistent with the recommendations of the physician or other health-care provider, the patient is thought of as being compliant. Poor compliance can take many forms, e.g., inattention to dietary or exercise recommendations, not taking the prescribed number of pills or taking them at irregular or otherwise nontherapeutic intervals, not refilling prescriptions, and not showing up at follow-up clinic visits. The focus of this review is on compliance to medication regimens.

Patients may be noncompliant for many reasons. The most obvious cause is simple forgetfulness, a more likely circumstance if a medication is being used for an asymptomatic condition such as hypertension. Alternatively, poor compliance may be a conscious decision based on undesired treatment side effects, on the patient's perception that the illness being treated is not serious, or on patient-specific beliefs about the potential impact of individual behaviors on health status. For example, one study of elderly

diabetics^[8] evaluated compliance to measures aimed at controlling diabetes using fasting blood sugar levels and diabetes-associated hospitalization rates as surrogates. Results indicated that improved control of diabetes was significantly associated with the belief that specific behaviors were likely to improve the status of one's disease and with the general perception that an individual's behavior can have a positive impact on health status. Additional reasons for poor compliance include the cost of the medication, the cognitive status of the patient, and the complexity of the drug-taking regimen. The latter two problems are particularly relevant in elderly patients who may be unable to follow the details of a series of medication schedules for multiple chronic conditions.

MEASURING COMPLIANCE

The traditional approaches to measuring compliance include biological markers such as plasma concentrations and urine assays, requesting the information directly from the patient, and using pill counts that reflect the content of returned pill bottles. Each of these approaches can provide useful information. At the same time, each has been shown to be inadequate in key respects: (1) by studies that yield different compliance rate estimates when assessments are carried out using two or more techniques; (2) by comparisons using the newest approach to quantifying compliance—electronic monitors.

The limitations of pill counts have been emphasized by several authors.^[9,10] For example, Pullar et al.^[9] assessed compliance by using both returned-pill counts and plasma concentrations of phenobarbital in 225 subjects. Among the 204 patients who returned for a scheduled follow-up visit with their pill bottles, 161 (78.9%) were classified as compliant because pill counts indicated that between 90% and 109% of prescribed medication had been taken. But 51 of these 161 patients (31.7%) had

doses and body-weight-corrected plasma phenobarbital concentrations that, according to predefined criteria, were indicative of poor compliance. Based on this large discrepancy between the two methods, the authors conclude that “return tablet count grossly overestimates compliance” and that the continued use of pill counts to measure compliance in clinical trials “cannot be justified.” The inadequacy of patient interviews in measuring compliance is highlighted by reports such as that of Norell,^[11] who summarizes data from four studies^[12–15] that measured compliance using both patient interviews and other more objective assessment techniques. The result was that interview noncompliance rates ranged from 12% to 31%, as compared with a range of 32–82% using the more objective approach. The interview produced the lower estimate of noncompliance by amounts that ranged from 20% to 65%. In another study, Caron^[16] reported that the average patient took 47% of the prescribed dose but claimed to have taken 89%.

In recent years, the development of microcircuitry has facilitated the use of miniaturized computer chips as electronic monitors that measure compliance by recording the date and time that medication is dispensed. These devices are now broadly accepted as providing the most accurate available measures of compliance. They have been attached to pill bottles,^[17,18] eye droppers,^[19] blister packs,^[20] and aerosol containers.^[21] They have also confirmed the observation that traditional assessment techniques often yield substantial overestimates of compliance. And, as we discuss next, they have provided important new insights into patterns of noncompliance.

MAGNITUDE AND PATTERN OF POOR COMPLIANCE

While some studies have reported excellent compliance rates as high as 90%,^[20,22] it is well documented that compliance to medication can often be quite poor.^[5,17,18,19] Good compliance tends to be associated with medications that have few side effects, with acute and symptomatic diseases, and with recent diagnoses. In the Physicians' Health Study,^[22] good compliance was likely a reflection of the motivation of an interested and highly educated sample. However, when compliance is poor, it can sometimes be in the range of 50% or less.^[5,19] Given that the standard methods for measuring compliance tend to yield overestimates, it is reasonable to expect that many reported noncompliance percentages are biased underestimates of the true magnitude of the problem.

While the number of doses taken may provide the best single measure of compliance to a prescribed medication regimen, it is not the only such measure. Indeed, it has become increasingly apparent that an accurate pill count may provide an inaccurate measure of patient compliance because drugs taken with the correct total dose may

simultaneously be taken at irregular and nontherapeutic intervals. Similarly, pill counts that are indicative of less than ideal compliance may understate the problem because of the same kind of irregular drug-taking patterns.

The dimensions and characteristics of irregular dosing can best be evaluated using electronic monitoring devices, which have demonstrated, for example, that compliance tends to improve in the days immediately preceding an office visit to the physician. Thus Cramer et al.^[18] found that compliance percentages were 88% during the 5 days immediately before a clinic visit but only 73% when no clinic visit was either imminent or had just taken place. Kass et al.^[19] found similarly that compliance rates were much higher during the 24-hr period preceding an appointment than during the rest of the observation period. One implication of these observations is that even if a biological marker provides an accurate estimate of compliance immediately prior to the assay, the marker may substantially overstate the general pattern of compliance because of the tendency of patients to be more compliant when they are about to see the doctor.

A further contribution of electronic monitors to an understanding of compliance patterns lies in the observation that “drug holidays,” sustained periods during which no medication is taken, are common.^[17–19] Thus De Klerk et al.^[17] studied the drug-taking patterns of 65 patients with ankylosing spondylitis who were prescribed once-a-day medication. The mean period of study was 225 ± 90 (SD) days, for a total of 14,607 monitored days. While 80% of prescribed doses were taken, only 61% were taken during the required 24 ± 6 hr. Extra doses were taken on 3.4% of days, while no dose was taken on 19% of monitored days. Among the nine subjects who had a high pill-taking rate of between 81% and 90%, four had a drug holiday of 13 or more consecutive days. In the Kass et al. study^[19] of 184 glaucoma patients being treated with four-per-day pilocarpine eye drops, the electronic monitor found that 24.5% of patients had at least 1 day per month with no administration of drug, while 52.7% of patients took five or more doses during at least one 24-hr period. Because the nighttime dose was omitted, 50% of the time in a study whose overall compliance rate was $76.0 \pm 24.3\%$ highlights the importance of patient-friendly drug-taking schedules as a compliance-enhancing strategy. The potential clinical impact of irregular drug-taking behaviors was demonstrated by Cramer et al.^[23] in an electronically monitored study of epilepsy patients that found a strong tendency for seizures to occur during the period after doses were missed.

One further aspect of drug-taking patterns is that there is an apparent tendency for compliance to decrease over time.^[5,22,24,25] Thus in the Physicians Health Study,^[22,24] compliance rates of 95.3% during a prerandomization run-in period were reduced to 83.8% during the study itself. The investigators in the Studies of Left Ventricular Dysfunction (SOLVD^[25]) reported that compliance rates were

80% at 1 yr, 74% after 2 yr, and 69% after 3 yr. The results of the 10-week follow-up period of the Vaginal Infections and Prematurity (VIP) Study^[5] are even more pronounced. In VIP, pill counts produced an estimated compliance rate of 85% during the first week of follow-up. But these rates decreased steadily to 47% during week 9 and only 43% during the final study week.

EFFECT OF POOR COMPLIANCE ON SAMPLE SIZE REQUIREMENTS IN CLINICAL TRIALS

When patients do not comply with a prescribed therapeutic regimen, a likely consequence is reduced treatment efficacy. But in the context of a clinical trial, reduced efficacy will yield a corresponding reduction in between-group differences and an associated increase in the required sample size. What is surprising in all of this is the magnitude of the potential sample-size increase.^[4-7]

To quantify the impact that partial compliance may have on sample-size requirements in clinical trials, Schechtman and Gordon^[4] employ both a hypothetical example and the detailed compliance data provided by the Lipid Research Clinics (LRC) Coronary Primary Prevention Trial.^[2,26] In the hypothetical example, the goal is to compare success rates in a clinical trial where the placebo-group success rate is 40% and the treatment-group success rate is 60% in patients who take all of their medication as prescribed. A compliant patient is one that takes at least 80% of the medication, and it is assumed that the success rate in the average compliant patients is 90% of the success rate in patients who take all of their pills. Using data from the LRC trial that translate into noncompliant patients having a cholesterol reduction of only 35.2% of the reduction in compliant patients, the hypothetical example assumes that noncompliers will receive 40% of the therapeutic benefit that is realized in compliers. Based on these assumptions, Table 1 provides a summary of Schechtman and Gordon's conclusions about the association between compliance rates and sample size. The results indicate, for example, that if the compliance rate is 70%, the sample size requirement is 1.84 times as great as it would be if all patients took all of their pills. The corresponding sample size ratio is 2.14 for a compliance rate of 60% and 2.52 if the compliance rate is 50%.

In the LRC trial,^[2,26] a treatment group that was prescribed six daily packets of cholestyramine resin, a cholesterol-lowering agent, was compared to a placebo group in a randomized double-blind trial involving 3806 hypercholesteremic men. The primary outcome measure was coronary heart disease (CHD) mortality. If the definition of compliance requires that the subject takes at least five of the six daily packets, then the reported compliance rate in the placebo group was 67.3%, as compared with 50.8% in the treatment group.^[2,4] Based on these compliance data, on the association between compliance

Table 1 Effect of Poor Compliance on Sample-Size Requirements

Percentage of patients who comply	Sample-size ratio
90%	1.40
80%	1.59
70%	1.84
60%	2.14
50%	2.52
40%	3.01

Data are from a clinical trial where the success rate is 40% among the placebo-group patients and 60% in the treatment-group patients who take all of their pills. It is assumed that the average complier receives 90% of the benefit of subjects who take all of their pills and that the average noncomplier receives 40% of the benefit of subjects who take all prescribed medication. The sample-size ratio is the ratio of the required sample size for the tabulated percentage of patients who are compliant to the corresponding sample size if all patients take all of their pills.

rates and cholesterol reduction in the LRC trial, and on the association between cholesterol reduction and CHD mortality, it was demonstrated^[4] that if the compliance rate in the treatment group (50.8%) had been as high as it was in the placebo group (67.3%), the sample-size requirement in the LRC trial would have been reduced by about 41%. Moreover, the required sample size with the observed compliance rate was 2.97 times as great as it would have been if all patients had been compliers.

EFFECT OF POOR COMPLIANCE ON THE CLINICAL STATUS OF PATIENTS

Poor compliance is a problem only if there is a causative relationship between not taking pills and the clinical status of patients. On the one hand, it seems intuitively likely that partial compliance to an effective medication will increase the probability of negative clinical consequences. But at the same time, the magnitude of this causative relationship is likely to heavily depend on case-specific considerations, such as the disease in question, the half-life of the drug, and the frequency with which medication is prescribed. Moreover, because compliance may be strongly associated with other behavioral factors that influence clinical outcomes, it may be difficult to determine the degree to which poor compliance, as opposed to the behavioral correlates of poor compliance, are the cause of negative patient outcomes. In the Coronary Drug Project,^[27] for example, compliers to the lipid-lowering agent clofibrate had a much lower mortality rate than noncompliers to clofibrate ($P = 0.0001$). The initial suggestion is that there is a strong causal relationship between clofibrate compliance and reduced mortality. But a further look at the data suggests caution because the same association between compliance and survival exists when placebo-group data are evaluated. Apparently, the reason for the reduced mortality among

Table 2 Data from the LRC Trial on Association Between Compliance to Medication and Cholesterol Reduction in the Cholestyramine Group and in the Placebo Group

Mean daily packet count	Placebo group		Cholestyramine group		Treatment effect
	N	Percentage change in cholesterol	N	Percentage change in cholesterol

The treatment effect column is the difference between the percentage change in cholesterol in the two groups.

compliers was not the drug. Instead, the real explanation may be that medication compliers in the Coronary Drug Project also tended to engage in routine daily activities that improve cardiovascular health.

The message in the preceding example is that when disease status is heavily influenced by patient behaviors other than compliance, it may be difficult to determine whether poor compliance or correlated behavioral factors are the cause of negative outcomes. With this caveat in mind, we illustrate the degree to which poor compliance can indeed have serious negative clinical consequences.

The LRC trial data on the association between compliance to cholestyramine and cholesterol reduction^[2] are summarized in Table 2. While the table exhibits a small dose–response relationship in the placebo group, the association between cholesterol reduction and the number of packets taken is far more pronounced in the cholestyramine group. This is highlighted by the treatment effect column of Table 2, which measures treatment benefit after subtracting off the cholesterol reduction in the placebo group. Thus in contrast to the Coronary Drug Project, the association between poor compliance and poor outcome can be overwhelmingly attributed to the direct causative effects of not taking the drug as prescribed. In combination with LRC data on the association between CHD events and cholesterol reduction, the treatment-effect column of Table 2 has been used to estimate the expected number of CHD events that would have been prevented if LRC compliance rates had been greater than they actually were.^[4] The observed number of CHD events in the LRC trial was 155 in the cholestyramine group and 187 in the placebo group, suggesting that the study medication prevented about 32 events. But because of the side effects of the drug, compliance to cholestyramine (50.8%) was much lower than compliance to placebo (67.3%), where compliance is defined as taking at least five of six prescribed packets. If compliance in the treatment group had been as high as it was in the placebo group, the expected number of treatment group events would have been 145, so the number of events prevented would have increased by an expected total of 10, from 32 to

42. And if one assumes that all cholestyramine patients are in the highest compliance category of Table 2, the expected number of events prevented is increased by 24, from 32 to 56. That is, full compliance to cholestyramine is associated with an expected 75% (24/32) increase in the number of CHD events prevented by the drug, in comparison to what actually happened in the LRC trial.

The literature contains numerous other studies that associate poor compliance with negative clinical consequences, such as increased hospitalization^[1] and reduced control^[20] in patients with hypertension, seizures in patients with epilepsy,^[23] increased mortality and organ rejection in transplant recipients,^[28] and increased coronary heart disease event rates when beta blockers are not taken.^[29] The magnitude of these negative consequences is highlighted by the Joint National Committee on Evaluation, Detection, and Treatment of High Blood Pressure, which asserts that noncompliance is the most important reason for uncontrolled high blood pressure;^[30] by a 1984 symposium on the therapeutic consequences of noncompliance, which suggested that 125,000 annual deaths result from noncompliance in patients with cardiovascular diseases;^[31] and by the U.S. Chamber of Commerce estimates that treating noncompliance-induced medical problems is associated with an annual cost of \$13–15 billion.^[32]

IMPROVING COMPLIANCE IN CLINICAL TRIALS

Since poor compliance to medication has the potential to substantially reduce treatment efficacy, it is not surprising that compliance-enhancing strategies are often a major component of clinical research. Broadly speaking, such strategies can be divided into two general categories—those that precede the initiation of study therapy^[2,5,22,24–26,33] and those that are implemented after randomization.^[2,26,34]

Compliance-enhancing strategies that precede randomization are usually focused on maximizing the likelihood that patients who enter the study will be good compliers. This is ordinarily accomplished using either a formal or

an informal run-in strategy. A run-in strategy is carried out during a prerandomization period during which the likely future compliance of the patient is assessed. This may be accomplished informally, as it was in the LRC trial,^[2,26] using a screening period during which patients are expected to attend prerandomization visits aimed primarily at determining eligibility and doing preliminary assessments. If the patient does not attend these sessions or is otherwise uncooperative, the conclusion may be that the patient should not be randomized because early behavior suggests future noncompliance. Alternatively, a formal run-in strategy may be carried out.^[5,22,24,25] A formal run-in involves a prerandomization period during which potential study subjects are asked to participate as if they had already been randomized. This specifically includes the taking of placebo medication and attendance at clinic visits that would be standard if the subject were to be randomized. Patients who do not comply up to some prespecified level are then excluded from the trial prior to randomization. It has been demonstrated that run-in strategies have increased the power of several major clinical trials.^[5,24] In general, run-in strategies are likely to be of benefit when poor compliance is associated with a substantial reduction in response, when poor compliance is common early in the study, when most early poor compliers could be expected to continue that pattern if randomized, when the run-in itself is inexpensive, or when the pool of eligible patients is sufficient to ensure that run-in exclusions will not compromise recruitment goals.^[35]

Compliance-enhancing strategies that follow randomization cover a broad range of potential activities and have been discussed by many investigators.^[36–40] These strategies include: educating patients about their disease and about the importance of compliance; financial and other incentives;^[40] simplified and flexible dosing regimens that are adjusted to fit individual patient schedules; establishing positive clinician–patient relationships; self-administered approaches, such as providing calendars to be checked off when doses are taken; specialized drug packaging, such as blister packs^[20] and caps for prescription containers that sound an alarm when it is time to take the next dose;^[38] and encouraging family members to provide support.

If there is any unifying theme in the investigation of these procedures, it is that no single approach can be successfully applied in all settings. Compliance-enhancing strategies must be tailored to the patient and to the particular circumstance. Their success depends heavily upon the ingenuity and the commitment of the health care provider.

CONCLUSION

Poor compliance prescribed medication is a common problem that can have negative consequences regarding both patient outcome and the conduct of clinical trials. The

magnitude of compliance can best be evaluated using electronic monitors which have demonstrated that compliance rates as low as 50% are not uncommon. In such a setting, treatment efficacy and between group differences are reduced, a circumstance which can lead to a doubling or even tripling of the required sample size in a clinical trial. More serious are the clinical consequences of poor compliance which have been demonstrated in a variety of studies to include increased mortality and hospitalization rates, reduced control of hypertension, increased seizure frequency in epileptics, and increased rejection rates in transplant patients. Because of these negative consequences, it is incumbent upon both clinicians and researchers to use all available compliance-enhancing strategies to encourage patients to take their medication in accordance with the prescribed regimen.

Patient-Reported Outcomes

Amylou C. Dueck, PhD

Mayo Clinic, Scottsdale, Arizona, U.S.A.

Joseph C. Cappelleri, PhD

Pfizer Inc., Groton, Connecticut, U.S.A.

Abstract

A patient-reported outcome (PRO) is any report directly from the patient about his or her health status or condition without interpretation by a clinician or anyone else. PRO data may be collected using patient-completed questionnaires or by interviews where the patient's response is directly recorded without modification. PROs have been developed to validly measure a variety of concepts (e.g., symptoms, well-being, health-related quality of life [HRQOL], and treatment satisfaction) for purposes such as assessing disease impacts as well as treatment benefits and harms. PROs are inherently important in this era of patient-centered healthcare and are common endpoints in randomized clinical trials in a variety of disease settings (e.g., asthma, irritable bowel syndrome, pain, arthritis, and cancer). The purpose of this entry is to provide a summary of statistical methods commonly employed for the analysis of PRO data in randomized clinical trials. The general approach to statistical analysis should mirror that applied to any other endpoint in clinical research. Specifically, the analysis plan should be based on the selection of an appropriate analytical method based on the stated hypothesis and distribution of the endpoint being analyzed. This entry outlines statistical approaches for cross-sectional and longitudinal comparisons. An overview of approaches for handling multiplicity and missing data is also presented.

Keywords: Quality of life; Health-related quality of life; Questionnaires; Surveys; Patient experience; Symptoms; Self-report.

INTRODUCTION

A patient-reported outcome (PRO) is any report directly from the patient about his or her health status or condition without interpretation by a clinician or anyone else. PRO data may be collected using patient-completed questionnaires or by interviews where the patient's response is directly recorded without modification. PROs have been developed to validly measure a variety of concepts (e.g., symptoms, well-being, health-related quality of life [HRQOL], and treatment satisfaction) for purposes such as assessing disease impacts as well as treatment benefits and harms. PROs are inherently important in this era of patient-centered healthcare and are common endpoints in randomized clinical trials in a variety of disease settings (e.g., asthma, irritable bowel syndrome, pain, arthritis, and cancer).

The purpose of this entry is to provide a summary of statistical methods commonly employed for the analysis of PRO data in randomized clinical trials. The general approach to statistical analysis should mirror that applied to any other endpoint in clinical research. Specifically, the analysis plan should be based on the selection of an appropriate analytical method based on the stated hypothesis

and distribution of the endpoint being analyzed, with careful considerations for handling multiple testing as well as missing data.

This entry outlines statistical approaches for cross-sectional and longitudinal comparisons. An overview of approaches for handling multiplicity and missing data is also presented. This entry is intended to expose readers to the myriad of appropriate statistical approaches. Key references for additional reading are given to further help readers to execute sound statistical analysis of PRO data in a randomized clinical trial.

PROs IN THE REGULATORY SETTING

The term “patient-reported outcome” or “PRO” is defined by the United States (US) Food and Drug Administration (FDA) as “a measurement based on a report that comes directly from the patient (i.e., study subject) about the status of a patient's health condition without amendment or interpretation of the patient's response by a clinician or anyone else.”^[1] The FDA identifies PROs as one of the four clinical outcome assessments (COAs) that directly or indirectly measure treatment

benefits from patients, clinicians (clinician-reported outcomes [ClinROs]), non-clinician observers (observer-reported outcomes [ObsROs]), or performance assessments (performance outcomes [PerfOs]).

PROs are unique from other outcomes because they can measure concepts that are unobservable to individuals other than the patient, concepts such as some symptoms (e.g., pain and fatigue) or HRQOL. PROs can also measure concepts such as physical functioning, which may be observable by others. The FDA's guidance document^[2] on the use of PROs for product labeling remains the gold standard for the statistical analysis of PRO data for product labeling purposes in the United States. The European Medicines Agency (EMA) released a reflection paper in 2005 detailing statistical recommendations for use of HRQOL in the drug approval process in Europe.^[3] The statistical methods presented herein represent a broader collection of analytical techniques not limited to those for the specific purpose of achieving a product label claim. Thus, the applicable regulatory recommendations as well as regulatory officials should be consulted to identify the specific recommended approaches if a product label is the intended goal of analysis.

DEFINING THE ENDPOINT

PRO data are typically captured using questionnaires that undergo rigorous development processes to ensure acceptable psychometric (i.e., measurement) properties in the given target patient population (see work by Reeve et al.^[4] for recommended minimum PRO standards). In addition to adequate measurement properties, other considerations when selecting among available questionnaires may include the proposed use of the questionnaire (i.e., hypothesis to be tested), the concept to be measured, patient and administrative burden, interpretability of scores, appropriateness for the given patient population (taking into consideration such things as age, disabilities, and comprehension level), availability of language translations, and costs. Formats of individual items or questions across questionnaires vary in terms of item wording, response options, and recall period (i.e., the period of time for which patients are asked to remember when responding to the item). Each questionnaire may contain one or more questions. Typically, each questionnaire has a scoring algorithm established during its development, which should be employed to calculate scores for statistical analysis when using the questionnaire in a trial. Depending on the questionnaire, scoring may result in a single overall score and/or scores for one or more individual items or subscales (or domains). When multiple domain scores are computable, each defined endpoint in the statistical analysis plan (SAP) should clearly specify the score to be used.

Selected questionnaires are often administered at multiple time points including prior to treatment, during, and/

or after treatment. Time points are often selected based on when changes or differences are expected to occur and typically synchronous with collection time points of other clinical data. See Fairclough^[5] for information regarding selection of appropriate time points for administering PRO questionnaires. Patient burden should be a key consideration in both selecting PRO questionnaires and time points in a trial.

With the PRO questionnaire, specific score of interest (if applicable) and time points identified, there are several options for defining an endpoint. For example, in a fictitious trial testing a new eight-week treatment for fatigue versus a placebo treatment in which the PRO questionnaire (e.g., a validated questionnaire that results in a single fatigue score on a 0–10 scale with higher scores representing worse fatigue) is administered prior to treatment and after two, four, six, and eight weeks of treatment, endpoints can be defined as the fatigue score at a fixed time point (e.g., at two, four, six, or eight weeks), a summary statistic which is computed across time points (e.g., best or average fatigue score observed across two, four, six, and eight weeks), or as the collection of longitudinal measurements over time. In trials testing treatments given for a limited duration, the appropriate endpoint typically reflects the final outcome of the trial (e.g., the final time point in which PROs are assessed). However, assessments during treatment may be useful to characterize the trajectory of responses within and between treatment arms.

In trials testing extended-duration treatments, such as advanced cancer treatments which are administered indefinitely until the patient's cancer progresses, an appropriate endpoint may be defined at a fixed time point which is both early enough in the trial so that most patients are still expected to be receiving treatment and late enough so that the treatment's impact is detectable. Often alternative endpoints employing summary statistics across time points or longitudinal measurements over time are also appropriate. In general, the selected endpoint in any trial should reflect the objective of the given analysis (i.e., answer the question being asked). Once an endpoint is defined, then an appropriate statistical analysis strategy can be selected.

CROSS-SECTIONAL ANALYSIS

For an ordinal or continuous PRO score at a fixed time point, comparison between two or more arms may employ standard parametric (e.g., two-sample t-test or analysis of variance) or non-parametric (e.g., Wilcoxon rank-sum test or Kruskal–Wallis test) analyses. Note, the central limit theorem insures appropriateness of parametric approaches, even for ordinal PRO scores with limited response options and with floor or ceiling effects for sample sizes as small as five per arm.^[6,7]

Other popular approaches to account for potential imbalances in baseline scores include computation of the

change from baseline or the percentage change from baseline for each patient with subsequent comparison between arms using the same parametric or non-parametric approaches. However, Vickers^[8] points out that these methods theoretically fail to protect from bias introduced by imbalanced baseline scores and that the percentage change from baseline approach can lead to non-normally distributed data. Vickers also showed that an analysis of covariance (ANCOVA) approach comparing the PRO score at the fixed time point between arms and including the baseline score as a covariate provided the highest power, making this a favorable approach for the comparison of an ordinal or continuous PRO score at a fixed time point (when no tangible bias from missing data is expected).

Multivariable linear regression can also be considered to model an ordinal or continuous PRO score with treatment arm, baseline score, and other baseline patient characteristics expected to be related to the postbaseline PRO score as predictor variables. Sullivan and D’Agostino^[9] depict that linear regression performs similarly to ordinal logistic regression for ordinal PRO scores even with relatively small sample sizes. For a binary PRO score at a fixed time point, arm comparisons may employ chi-squared or similar tests, or a logistic regression-based approach, including treatment arm and baseline patient characteristics expected to be related to the postbaseline PRO score as predictor variables.

SUMMARY MEASURES AND STATISTICS

One of the methods for inferential purposes is to use summary measures or summary statistics. For instance, a single measure can be constructed by aggregating data across different domains on the same questionnaire if such aggregation is justified clinically and statistically. Such a summary measure can be used as the primary endpoint for hypothesis testing.

Summary statistics can be constructed on a particular subscale or domain of an instrument to summarize its repeated observations over time within an individual and then across individuals in the same treatment arm. Examples include, for each treatment arm, the average of the within-subject average, maximum, minimum, or last observed postbaseline score; the within-subject least-squares estimated slope across postbaseline scores; within-subject area under the curve (AUC); and within-subject time to reach a peak or a prespecified value.

Use of summary measures and statistics can serve several purposes. These endpoints can aid in interpretation as well as handle multiple testing by combining data across scales and/or time points into a single score. They can also be an analysis strategy for minimizing missing data because a patient can often be evaluable even if the patient missed an assessment time point. However, caution should be taken to consider any bias introduced by missing data on

these endpoints. Caution should also be taken when using summary measures and statistics to ensure that high-level summarization does not obfuscate important differences in individual scales and/or time points.

Area Under the Curve

One clinically intuitive summary statistic is the AUC. An AUC can be computed for each individual patient by connecting observed scores (Table 1) longitudinally over a fixed period of time, computing the area of each resulting trapezoid, and summing the areas of these sequential trapezoids (Fig. 1). AUCs (computed for each individual

Table 1 Sample dataset (first two patients are shown)

PatientID	WEEK	ARM	FATIGUE
1	0	1	6
1	2	1	7
1	4	1	5
1	6	1	4
1	8	1	5
2	0	1	7
2	2	1	6
2	4	1	5
2	6	1	4
2	8	1	2
...	...	...	...

Fig. 1 Example of patient-level area under the curve calculation. Area under the curve is calculated for PatientID = 1 in Table 1. The areas of the trapezoids from left to right are 13, 12, 9, and 9 for a total area under the curve of 43. In this example, the minimum and maximum possible AUCs are 0 and 80, respectively. Therefore, the AUC of 43 can be interpreted relative to this 0 (no fatigue over the entire eight weeks) to 80 (worst possible fatigue over the entire eight weeks) scale

patient) can then be compared between arms using the previously described cross-sectional approaches. While intermittent missing data are typically handled by connecting only observed scores, missing data at the end of the fixed time period due to dropout have been handled in various ways including single imputation strategies (see Bell et al.^[10] for a summary of such methods). Bell et al.^[10] suggest that an arm-level AUC approach (i.e., computing the AUC for each arm using parameter estimates from a mixed model and comparing these between arms using a contrast) is less biased than comparing within-subject AUCs computed for each individual patient in the presence of dropout.

Responder Analysis

Another popular summarization approach is a responder analysis where a threshold is a priori defined as a clinically meaningful change (i.e., improvement) from baseline in a PRO score. Let us assume that higher scores are more favorable. Then a patient can be classified as a responder if the patient's change score meets or exceeds the selected threshold. Typically, all other patients are considered as non-responders including patients without PRO data available for analysis. This binary outcome is then compared between arms using a chi-squared or similar test. The clinically meaningful improvement is typically specific to the given PRO score, patient population, and trial context (see Wyrwich et al.^[11] for an overview of anchor-based and distribution-based methods for establishing clinically significant change thresholds).

Patients for whom the change threshold is not analytically possible can be excluded from responder analysis. For example, say that response is defined as a 2-point symptom improvement on a 0 = none, 1 = mild, 2 = moderate, 3 = severe, or 4 = very severe scale. Responder analysis would exclude patients reporting no or mild symptom level at baseline. If responder analysis is the primary (or key secondary) analytical approach for the trial, study inclusion criteria can be defined so all subjects have the opportunity to reach the prespecified clinically defined improvement. For instance, all subjects in pain trials are typically required to have at least a baseline pain score of 4 or 5 on an 11-point scale (0 = no pain, 10 = worst imaginable pain).^[12] If study inclusion criteria do not limit enrollment in such a way, power may be compromised if a substantial proportion of patients are not eligible for the planned responder analysis.

The main advantage of responder analysis is ensuring that a statistically significant result represents a clinically meaningful benefit. The disadvantages include the possibility of an increased sample size due to the loss of information associated with reducing a continuous outcome to a binary outcome. Threshold selection can also be somewhat arbitrary. Finally, interpretation can be problematic if response is only a temporary phenomenon.

Fig. 2 Example of a cumulative distribution function plot. Negative change scores represent improvement. The solid curve represents ARM = 1 (active treatment arm) and the dashed curve represents ARM = 2 (placebo arm). At a change score of -2 (i.e., a 2-point improvement in fatigue on a 0–10 scale where higher scores represent worse fatigue), 82% of patients on active treatment versus 52% of patients on placebo experienced at least a 2-point improvement (i.e., a change score less than or equal to -2)

Supplemental analysis following any responder analysis should include assessing the impact of the selected responder definition on trial results. A graphical approach is a cumulative distribution function (CDF) plot by arm achieved by plotting the change thresholds on the x-axis and cumulative percentage of patients meeting or exceeding each threshold on the y-axis (Fig. 2). Patients who do not have PRO data available for analysis can be considered to have the worse change possible or simply considered as missing if justified. The CDF plot allows comparison between arms at every possible threshold simultaneously. Horizontal separation between CDFs of two arms supports the trial's results as being consistent across the entire range of thresholds. When CDFs overlap or crisscross, interpretation can be challenging but may be aided by a focus on clinically plausible thresholds. Proper statistical analysis of the full original scale is generally recommended with responder analysis considered as supplementary analysis.

Time to Significant Worsening or Improvement

Another summary statistic transforms longitudinal PRO data into time-to-event endpoints. Time from baseline until a clinically meaningful worsening (or improvement) can be computed for each patient. Patients without clinically meaningful worsening are typically censored at the last completed PRO assessment. Time-to-event data can be analyzed using Kaplan–Meier plots with log-rank tests or Cox regression. Like responder analysis, a threshold

representing clinically meaningful worsening or improvement should be specified a priori.

In some palliative care and/or cancer settings, disease progression and/or death are included along with PRO worsening as events (e.g., see Benzo et al.^[13]). In interpreting such an analysis, researchers should consider whether differences between arms are driven by clinically meaningful worsening of PRO scores, progressions, or deaths. Considering each endpoint separately in addition to the combined endpoint (PRO worsening, progression, or death) may aid in interpretation.

LONGITUDINAL ANALYSIS

Regression-based analyses for longitudinal PRO data are a popular and well-described analytical strategy to analyze both within-arm and between-arm changes in PRO scores over time.^[15] Such modeling approaches do not differ from those described and standardly used for other longitudinal quantitative data.^[14] Some have argued that longitudinal analysis is the preferred analysis strategy over previously described fixed time point analyses in trials with longitudinal measurements.^[15] Prior to embarking on longitudinal modeling, researchers should carefully inspect descriptive statistics such as means over time by arm, within-time point variance, and between-time point covariance to aid in proper selection and design of a longitudinal model. Longitudinal models for PRO data generally fall into two broad categories, event-driven and time-driven models where time is an ordered categorical and continuous predictor variable, respectively.

A common event-driven model is the repeated measures model. This model requires each PRO score be assigned to a discrete time point with only one PRO score per patient assigned to each event. In its simplest form, the PRO score is modeled using an intercept, fixed time effect, and fixed treatment (arm) effect with a random error term which accounts for repeated measurements within subject. A common time-driven model is the random coefficient model or mixed effects growth curve model. Time-driven models can accommodate all assessments regardless of time and can incorporate the actual timing of the assessment. Models typically include a random individual-specific intercept term with or without a random individual-specific slope term, as well as a random error term.

An unstructured covariance matrix does not assume any pattern among errors and does not assume equally spaced time points like other covariance structures such as first-order autoregressive structure. Therefore, it is a flexible and reasonable default selection for event-driven and time-driven models if sample size allows for such. However, it may be desirable to reduce the number of parameters being estimated. Alternative covariance structures from among theoretically plausible structures can be selected based on optimization of model fit criteria such as

Table 2 SAS v9 code for generating simple forms of longitudinal models using data in Table 1. Many variations on these models are possible (e.g., see Fairclough^[5]), such as inclusion of WEEK*ARM interaction terms to allow the impact of ARM to change over repeated measures or time and modeling postbaseline scores only while including the corresponding baseline score as a covariate, to name just two. CONTRAST and ESTIMATE statements can be used within PROC MIXED to set up a variety of hypothesis tests assessing between-arm differences or within-arm changes at specific time points or across time points or even model-based calculations of area under the curve

Description	SAS Code
Repeated measures model (time is a categorical variable)	proc mixed data=dataset1; class WEEK ARM PatientID; model FATIGUE = WEEK ARM / solution ddfm=kr; repeated WEEK / subject=PatientID type=UN r corr; run;
Random intercepts model (time is a continuous variable)	proc mixed data=dataset1; class ARM PatientID; model FATIGUE = WEEK ARM / solution ddfm=kr; random intercept / subject=PatientID type=UN; run;
Random intercepts and slopes model (time is a continuous variable)	proc mixed data=dataset1; class ARM PatientID; model FATIGUE = WEEK ARM / solution ddfm=kr; random intercept WEEK / subject=PatientID type=UN; run;

Akaike information criterion when the same model effects other than the covariance structure remain constant across models (e.g., see Littell et al.^[16]). Longitudinal models can be implemented in SAS, SPSS, Stata, and R (see Table 2 for SAS v9 code). Modifications to models can account for non-linear changes over time such as using polynomial terms or piecewise linear splines. Finally, use of the general estimating equations (GEE) approach, which is an extension of generalized linear models, is commonly employed when modeling binary or count-based PRO data as well as continuous data (see Fitzmaurice et al.^[14] for further information regarding GEE and how it differs from repeated effects and mixed effects models).

MULTIPLE TESTING

Like all other statistical analyses in clinical research, performing multiple PRO hypothesis tests inflates type I error. Multiplicity is a common concern in trials with PROs due to questionnaires producing multiple scale scores, use of multiple PRO questionnaires within the same study, and PRO measurement at more than one time

point during treatment. Multiplicity may also arise from multiple arms within a trial or multiple planned subgroup analyses. One should always consider the study objectives/hypotheses before making a decision to apply a method for handling multiplicity (i.e., though many possible PRO hypotheses could be tested in a study, only one or some may be of interest). If a method is needed, standard methods for handling multiplicity are readily available for use in the analysis of PROs.^[17] The selected approach may be influenced by the trial setting. For example, within a trial intending to support a label claim, strict control of type I error may be required across all PRO and other clinical endpoints that are measuring treatment benefits. Outside of the label claim setting, multiplicity may be considered for PRO endpoints separately from other endpoints. In early-stage clinical trials, relaxed control of type I error may be appropriate as subsequent confirmation is expected.

Arguably, the most common approach for handling multiplicity in trials with PRO endpoints is a specification of a single hierarchy consisting of primary, secondary, and exploratory endpoints. Gatekeeping, fixed sequence, and fallback approaches perform hypothesis tests sequentially in this protocol-specified hierarchy, the simplest of which consists of each hypothesis test being performed as long as the previous hypothesis test reached statistical significance (i.e., $p\text{-value} < 0.05$). Once a hypothesis test fails to reach statistical significance, then no formal subsequent tests are performed. In practice, all subsequent statistical tests should still be carried out and reported with the gatekeeping approach incorporated for interpretation purposes.

Other methods for handling multiple endpoints include alpha adjustment methods (e.g., Bonferroni, Hochberg's step-up, and Bonferroni–Holm's step-down methods) and resampling methods. The Bonferroni approach is considered the most conservative, while Hochberg's method is recommended though still conservative like alpha adjustment methods in general. Resampling methods take into account relationships among test statistics and are, therefore, considered less conservative. Another alternative is to allocate different type I error rates to more than one endpoint (e.g., allocate 0.03 to one endpoint and 0.01 to each of two other less important endpoints for a total maximal type I error rate of 0.05).

As previously discussed, summary measures and statistics that combine data across scales and time points, respectively, may also be an appropriate method for handling multiple testing by reducing the number of statistical tests down to a single comparison of the summary measure or statistic. Finally, a variety of multivariate methods perform an overall hypothesis test (i.e., produce a single $p\text{-value}$) across a collection of endpoints to avoid multiple testing. O'Brien's global test is a non-parametric approach for testing whether multiple outcomes consistently differ between arms in the same direction. Hotelling's T^2 or multivariate analysis of variance are parametric alternatives; however,

these approaches test for differences between arms in any direction leading to the possibility that a significant test may be driven by differences in opposing directions (i.e., favoring one arm for one endpoint and the other arm for a different endpoint). For this reason, O'Brien's test is preferred. Global tests are further described by Wassmer et al.^[18]

MISSING DATA

Missing data in clinical trials are ubiquitous for most (if not all) endpoints including PROs. Missing data are a problem for two main reasons. First, a reduced sample size impacts power for planned statistical tests. Second, missingness is often informative and can bias arm comparisons even if the rate of dropout between arms is similar. Much methodological work has been conducted to develop methods for handling missing PRO data.^[5,19] Patients miss assessments due to a variety of reasons including, but not limited to, missed appointments, hospitalizations, staff forgetting to administer the questionnaire, patient dropout due to no longer being ill or being too ill, and death. Patients may also miss individual questions within a questionnaire inadvertently or on purpose for reasons such as feeling too ill to complete all questions or perceiving items to be not applicable, difficult to understand, or uncomfortable to answer.

The best approach to handling missing data is to minimize missing data prospectively. This approach is far superior to all analytical methods for handling missing data “after the fact,” i.e., during the analysis phase. Approaches to minimize missing data prospectively include careful design, staff training, and real-time monitoring of data. PROs should be treated in the protocol with as much attention and importance as other clinical trial endpoints, including integrating PRO administration time points into the main study calendar. Also, individuals at each site should be identified to be responsible for all PRO aspects of the study. Administration should be standardized including training of site staff to check for skipped pages in paper-based questionnaires and having a back-up data collection method in the event of a missed questionnaire such as following up by telephone, mailing a back-up questionnaire, or administering a questionnaire at the next clinical visit. Ensuring professional-looking format, convenient timing, understandable and applicable questions, and feasible length of PROs can also improve compliance. Electronic PRO administration can also enhance compliance through automated patient reminders, allowing response at a time which is convenient to the patient, and real-time site notifications for missed assessments. Finally, real-time monitoring of PRO compliance can identify site-specific issues, which can be remedied to improve compliance rates moving forward. Strategies and design considerations for minimizing missing data are detailed by Fairclough^[5] and Little et al.^[20]

Data elements that will be required to understand or handle missing data should be identified. Reasons for missed PRO assessments should be collected in order to better understand the missing data mechanism. Other data elements include the date/time of the assessment, mode of administration (if questionnaires are being administered through more than one mode), other administration details including whether a proxy was used to capture the data, and auxiliary data if you plan to use it in your SAP to address missing data. Auxiliary data are variables that are associated with the outcome being modeled and are available even when the outcome is missing.^[21] For example, a physician's rating of a patient's Eastern Cooperative Oncology Group (ECOG) performance status, which is systematically collected at every visit in many cancer trials, could be considered as "auxiliary data" in modeling patient-reported physical functioning. A caregiver's or other proxy's rating for a given scale could also be used as auxiliary data.

For missing individual items within a questionnaire, scoring algorithms often allow for some missingness. Some algorithms require at least half the items in a scale be completed by the patient and rely on simple mean imputation. If the scoring algorithm does not specify how to handle individual missing items, the previously described approach may be appropriate depending on the nature of the scale. Alternative imputation strategies depending on the scale may include logical imputation. For example, in the Patient-Reported Outcomes version of the Common Terminology for Adverse Events (PRO-CTCAE, www.healthcaresdelivery.cancer.gov/pro-ctcae/), different items assess the frequency, severity, and interference of the symptoms. If the patient responds as not having the symptom of interest in the first question and omits responses to the follow-up questions about the same symptom, a reasonable approach would be to impute a value of 0 (i.e., no severity and no interference) for the missing items. See Fayers et al.^[22] for a description of other approaches as well as a framework for handling missing data at the item level.

For missing data at a scale level, a scale that is missing completely at random (MCAR) is one in which the probability of missingness is unrelated to its value. A scale that is missing at random (MAR) is one in which the probability of missingness only depends on past covariates or its past values. Finally, a scale that is missing not at random (MNAR) is one in which the probability of missingness is related to its own value even after accounting for past covariates and its past data values.

The first step in analysis is to understand the extent and patterns of missing data (Fig. 3) and the reasons for missingness. Baseline covariates can also be compared using standard statistical methods such as two-sample t-tests and chi-squared tests between patients with and without missing data for a given analysis to assess for bias. Likelihood of a missing assessment and time to dropout can also be modeled using logistic regression and time-to-event analysis, respectively.

Fig. 3 Plot of mean fatigue scores for ARM = 1 stratified by last visit. A higher score represents worse fatigue. The triangle markers represent the subgroup of patients who completed the trial (N = 120). The circle, square, diamond, and star markers represent the subgroups (N = 20 each) of patients who completed six, four, two, and zero weeks of the trial, respectively. Based on this plot, patients who dropped out early tended to experience worsening after initial improvement or lack of improvement prior to dropout, whereas the patients who completed the trial on average had continual improvement over the course of the trial

The recommended analytical approach to handle missing data is to incorporate all patient data that is available and use a method which assumes MAR in primary analysis, followed by various sensitivity analyses which assume other missing data mechanisms. Results across sensitivity analyses should be descriptively compared to assess the robustness of trial results across varying missing data assumptions. Methods that assume MCAR should only be used when justified. These methods include complete case analyses as well as repeated univariate analyses, both of which include only patients with complete data. Similarly, excluding large numbers of patients (e.g., requiring a certain number of assessments during treatment) should be avoided.^[7]

Common methods that assume MAR include maximum likelihood modeling (e.g., previously described repeated measures or mixed effects growth curve models) and multiple imputation. Multiple imputation is a general framework where missing data values are filled in with likely values multiple times using a regression model and then results from these multiple imputed datasets are combined using Rubin's method.^[23] Multiple imputation is preferred to single imputation (impute a single value instead of multiple values) to ensure that variance is properly inflated to account for the added error due to imputation. However, imputation methods may decrease power and may not control the overall type I error rate to the desired level due to the variability associated with the imputed data. While MAR methods may result in some bias when data are not

missing at random, MAR methods are often robust when estimating differences between arms if observed covariates or earlier scores reflect the likelihood of subsequent missingness.

While missing data in PRO studies are often MNAR, several methods convert the MNAR problem into a lesser MAR problem. These methods include imputation approaches which incorporate auxiliary data (e.g., caregiver or proxy data) so that conditional on this auxiliary data the missing data are MAR. Pattern mixture models assume MAR within each pattern. Joint models assume MAR conditional on jointly modeled outcomes. An alternative approach, which is relatively less dependent on assumptions, involves searching for a tipping point that reverses the study conclusion.^[24]

OTHER ANALYTICAL CONSIDERATIONS

Stratification and clustering can be incorporated through appropriate model-based methods. Like other endpoints in clinical trials, the intent-to-treat approach (i.e., inclusion of all enrolled subjects with treatment analyzed according to the randomized assignment) should be considered the gold standard as analyses are unbiased due to randomization and estimate the true effectiveness of the treatment being tested. However, in some situations, per-protocol analysis (i.e., inclusion of enrolled subjects who receive treatment per protocol specifications) may be warranted, but is subject to selection bias so should be interpreted with extreme caution.

Additional PRO analyses incorporated into some trials include concurrent validation analyses (e.g., Mesa et al.^[25]). These analyses intend to assess or confirm PRO measurement properties using clinical trial data, e.g. when limited data exist within the given trial context. Typically, these analyses require supplemental data collection (e.g., patient global impression of severity or change scales).

Analysis of quality-adjusted life years (QALYs) is another analysis performed commonly as part of cost-utility or decision analysis and requires survival data and patient-reported health utilities such as those measured using EuroQOL's EQ-5D questionnaire. Health utility values tend to range from -1 to 1 (perfect health), with 0 representing death and negative values representing health states worse than death. QALY analysis weights the quantity of survival by the quality of survival to compute a single value for analysis across health states. The patient-level QALY can be computed per patient as the weighted sum of times spent at each utility level (see Billingham et al.^[26] for information about incorporating discounting of later benefits and/or handling change in utility measures between assessments).

When there is no censoring in the survival outcome, then statistical analysis can be based on usual methods such as a two-sample t-test. If there is censoring, then either QALYs

can be computed for each patient over the same fixed time period prior to any censoring or a model-based approach can be used to compute arm-level QALYs. Arm-level QALYs can be computed per arm using information from the Kaplan–Meier survival curve and repeated measures model of utility scores and then be compared between arms using a bootstrap or similar approach.^[27] Quality-adjusted time without symptoms or toxicity (Q-TWiST) method is a related method, which partitions survival into three health states.^[28] Beyond the PRO analyses described herein, many other correlative and supplemental analysis methods exist for assessing the relationships among PROs; mediating effects of PROs on other outcomes;^[7] or jointly modeling PRO data with other outcomes such as survival.^[29]

REPORTING OF RESULTS

Once analysis is complete, then results should be properly reported. The CONSORT-PRO extension expands on required elements in manuscripts of randomized trials to include key details pertaining to PROs.^[30] There are five additional checklist items specific to PROs beyond the standard CONSORT recommendations. These include that PROs be identified as a primary or secondary outcome in the abstract; PRO hypotheses be stated; measurement properties of the PRO questionnaire be provided or cited; statistical approach for dealing with missing data be explicitly stated; and PRO-specific limitations and generalizability be discussed. The modified CONSORT diagram (see supplemental content associated with the work of Calvert et al.^[30]) also includes specifying particular reasons why PRO assessments were not completed and the samples sizes for PRO analyses.

CONCLUSIONS

The vast majority (if not all) statistical methodologies described throughout this entry are not unique to PRO analyses, supporting the premise that development of a SAP for a PRO endpoint should be similar to that of any other clinical trial endpoint. Specifically, the plan should be based on the selection of an appropriate analytical method based on the stated hypothesis and distribution of the endpoint being analyzed with careful considerations for handling multiple testing and missing data. PRO questionnaires should be scored using the validated scoring algorithm and preliminary analysis should include descriptive statistics to understand trajectories of scores over time by arm; extent of missing data, its patterns, and causes; and potential selection biases in those patients who are providing PRO data.

For analysis of an ordinal or continuous PRO endpoint at a fixed time point, a recommended approach is to consider ANCOVA adjusting for baseline scores (when missing data

are not a real factor) or longitudinal modeling (with the estimate made at the fixed time point of interest). Parametric approaches are generally acceptable for ordinal PRO data even when sample size is modest. Summary measures and statistics, while seemingly useful due to allowing simplified analysis and interpretation of a single score, should be used judiciously as such measures may be impacted by missing data “behind the scenes.” In general, responder analysis should be considered as supplementary analysis to augment analysis of the full original scale. Regression-based analyses for longitudinal PRO data are effective and flexible strategies to analyze both within-arm and between-arm changes over time with models incorporating time as either a discrete or continuous event. Unstructured covariance is a reasonable approach in most cases.

Multiplicity is most commonly addressed through specification of a hierarchy of endpoints, either within all clinical endpoints of the trial for strict control or within the subset of PRO endpoints for less strict control depending on the setting. The singly best approach to handle missing data is prospective minimization of missing data. The recommended method to handle missing data once reaching the analysis phase is to use all available patient data along with a primary analysis method, typically one that assumes MAR, like repeated measures or random coefficient models, with sensitivity analyses performed. CONSORT-PRO extension should be followed for judicious reporting from clinical trials.

Abstract

This entry reviews two major approaches for estimating percentile curves of single variables, discusses the issue of joint estimation with two or more correlated variables (e.g., blood pressures and measures on four Serum Immunoglobulin G subclasses), and points the readers to more recent work on conditional growth charts.

Keywords: Box-Cox transformation; Growth charts; Percentile curves; Quantile regression.

INTRODUCTION

Percentile (or centile) charts are often used in health monitoring, medical screening, and clinical studies. In typical applications, a health professional compares certain physical or medical measurements taken from a particular subject with age-specific reference curves to detect extreme readings. The construction of reference curves is generally made from a sample of relevant subjects. When a very large sample is readily available, a purely nonparametric method may be employed by calculating various percentiles for each age group of interest. In most applications, however, we are limited in sample sizes and cannot obtain good estimates of the extreme percentiles at all ages without additional assumptions. In this paper, we review two major approaches for estimating percentile curves of single variables, discuss the issue of joint estimation with two or more correlated variables (e.g., blood pressures and measures on four Serum Immunoglobulin G subclasses), and point the readers to more recent work on conditional growth charts.

BOX-COX TRANSFORMATION

The Box-Cox transformation to normality is one approach commonly used in estimating conditional quantile curves. Suppose that y is the variable of interest. The percentile charts often consist of several percentile curves of y as a function of time. In general, we consider $Q_\tau(x)$, the τ -th conditional quantile of y given a set of covariates x , where τ is a value between 0 and 1, indicating a desired percentile level. The Box-Cox transformation operates under the assumption that $y(\hat{a}) = (y^{\hat{a}} - 1)/\hat{a}$ is normally distributed with mean μ_x and variance σ^2 for some unknown power

parameter $\hat{a}$. The special case of $\hat{a} = 0$ is taken to mean a log transformation. It is then easy to obtain that

$$Q_\tau(x) = ((\mu_x + \sigma z_\tau)\hat{a} + 1)^{1/\hat{a}},$$

where z_τ is the τ -th quantile of a standard normal distribution. If $\hat{a} = 0$, we simply have $Q_\tau(x) = \exp(\mu_x + \sigma z_\tau)$.

The literature is rich on the Box-Cox transformation to normality. Theoretically, $y(\lambda)$ cannot be exactly normal except in the special cases of $\lambda = 0$ or 1. In practice, we expect the transformed variable to be approximately normal. Maximizing the normal likelihood leads to a transformation that renders $U(\hat{a})$ as close to normal as possible under the Kullback-Leibler information number, see, [1–3]

For example, consider serum IgG (Immunoglobulin G) subclass concentrations for children. Recent developments on radial immunodiffusion using monoclonal antibodies have made possible rather accurate measures on four known subclasses of IgG (assigned IgG 1–4). Deficiencies of one or more IgG subclasses are associated with recurrent infections in children, see, [4–6] As the scope of IgG subclass measurements as a diagnostic tool has increased since the early 1980s, health professionals in various countries have found it useful to establish the percentile ranges for their own populations, see, [7–10] for example. All these researchers employed Box-Cox transformations in their work with $\mu_x = x'\beta$ for some unknown parameter β .

The power transformation approach has been generalized by Cole, [11] and Cole and Green, [12] allowing the transformation parameters to be a function of the covariate (e.g., age). It is based on the assumption that $(y^{l(x)} - m(x))/s(x)$ is approximately $N(0, 1)$ for three unknown but smooth functions $l(x)$, $m(x)$, and $s(x)$, which can be estimated by the penalized likelihood method. This is called the LMS

method, with the three letters of the name referring to the functions $l(x)$, $m(x)$, and $s(x)$. One attraction of this LMS method is that it allows local transformations that are age-dependent. Wright and Royston^[13] compared several statistical methods. They also extended the transformation method by using fractional polynomials in Ref. [14].

QUANTILE REGRESSION

Quantile regression of Koenker and Bassett^[15] provides another way to estimate percentile curves without any distributional assumptions on the response. For each level τ we assume that $Q\tau(x)$ is a parametric or non-parametric function of x . Quantile curve-fitting techniques can be found in Refs. [16,17]. This approach can be especially useful if a power transformation towards normality is unrealistic. A recent demonstration of this approach using spline approximations to smooth curves can be found in Ref. [18], where it was shown that features such as bimodality in the data will be better captured with quantile regression.

A full-scale comparison between the transformation approach and the quantile regression approach is lacking; however, both methods have been quite well studied so that the following points can be made. A transformation-based method leads to lower variance in estimating extreme percentiles. The quantile regression method does not assume any distributional information globally, so it has higher variability when τ is close to 0 or 1. On the other hand, it may be

difficult to judge whether a transformation of y has successfully made it close to being normally distributed, especially in the tails, so the lower variability in the extreme quantiles may have come at the cost of larger bias. The quantile regression approach has the advantage that the estimated τ -th quantile will divide the sample into the desired τ : $(1 - \tau)$ ratio. Since the transformation method estimates certain global parameters from the sample, it is less robust against outliers. A combination of transformation and linear quantile models has been studied in Ref. [19], but this method has not been used in the construction of percentile charts.

CORRELATED RESPONSE VARIABLES

All the work cited above focused on percentile curve estimation for one variable at a time ignoring information possibly contained in available variables of equal interest. In the IgG literature such as those ^[7-10] cited above, marginal estimation was used for each IgG subclass without consideration of the correlations among those subclass measurements. In other applications involving, say, weight and height or systolic and diastolic readings in blood pressure, the correlation can be quite significant. He, Ng, and Shi^[20] investigated whether the common practice of separate percentile curve construction, referred to as the *marginal* method, can be improved upon by *joint* estimation that takes possible correlation among variables into account. Figure 1 is a graph of the root mean

Fig. 1 Box-Cox transforms for dependent variable IgG1 in a quadratic regression of IgG1 on age: root mean square error against λ . The smallest value of RMSE is achieved at $\lambda = 0.40$

square error (RMSE) of the quadratic regression of IgG1 on age against different value of λ for the Example 1 of.^[20] The optimal λ in the figure is $\lambda = 0.40$, which was adopted in univariate Box-Cox transform in Ref. [20].

When there are several variables of interest, percentile contours may be defined in the multivariate context, and indeed there has been active research in this direction.^[21,22] Still, screening by individual variables (e.g., IgG subclasses) remains relevant and percentile regions of common forms do not directly reduce to a valid percentile interval. In this section, we follow^[20] to focus on percentile charts of individual variables based on the Box-Cox transformation to joint (multivariate) normality and compare this with the marginal method. Other tools will be briefly discussed in the concluding section.

For multivariate data without covariates, several authors have addressed this issue with partial conclusions. Johnson and Wichern^[23] represented an extended belief that it is not so worthwhile to maximize the joint normal likelihood given the additional cost of computing, which was certainly an important factor in those earlier years. In a somewhat related context, Koenker and Portnoy^[24] reached a similar conclusion for estimating regression medians. On the other hand, Velilla^[25,26] demonstrated that the joint approach leads to better efficiency and better diagnostics. For the bivariate case, the asymptotic efficiency of a joint estimate relative to a marginal estimate can be as high as 1.5.

To provide a clearer understanding of how the joint and the marginal methods compare, we follow^[20] to present in a general set-up for the multivariate Box-Cox transformation model in regression.

We consider p response variables $y_1, \dots, y_p$ that satisfy the following modeling assumptions:

$$y_i(\hat{\alpha}_i) = x' \beta_i + e_i, \quad i = 1, \dots, p \quad (1)$$

where x is the m -dimensional covariate, $\beta_i \in R^m$ are unknown parameters, and $(e_1, \dots, e_p)$ are expected to be close to multivariate normal with mean zero and variance covariance matrix Σ . The parameters $\theta_i = (\hat{\alpha}_i, \beta_i, \sigma_i)$ have to be estimated based on a sample of n observations $(x_j, y_{ij})(i = 1, \dots, p, j = 1, \dots, n)$.

Let Y_j denote the column vector of $(y_{1j}, \dots, y_{pj})$, $B = (\beta_1, \dots, \beta_p)$, and θ denote the vector of all parameters concerned. The joint log-likelihood (up to a constant) is

$$l_j(\theta) = -\frac{1}{2} \sum_{j=1}^n (Y_j(\hat{\alpha}_i)' - x_j' B) \sum_{i=1}^p (Y_j(\hat{\alpha}_i)' - x_j' B)' - \frac{n}{2} \log \left| \sum \right| + \sum_{i=1}^p \sum_{j=1}^n (\hat{\alpha}_i - 1) \log y_{ij}. \quad (2)$$

By forcing Σ to be a diagonal matrix in (2), we can decompose the log-likelihood as a sum (over i) of the marginal log-likelihood for the i th variable

$$l_j(\theta_i) = -\frac{1}{2\sigma_i^2} \sum_{j=1}^n (Y_{ij}(\hat{\alpha}_i) - x_j' \beta_i)^2 - n \log(\sigma_i) + (\hat{\alpha}_i - 1) \sum_{j=1}^n \log y_{ij}. \quad (3)$$

The marginal method maximizes $l_i(\theta_i)$ for each i to find the transformation. For both methods, the estimators of θ are asymptotically normal, but the asymptotic efficiencies differ. For example, we consider a simple logarithmic model with $p = 2$, $m = 1$, $E(x) = 0$, $Var(x) = 1$, $(\hat{\alpha}_1, \hat{\alpha}_2, \beta_1, \beta_2, \sigma_1, \sigma_2, \rho) = (0, 0, 0, 0, 1, 1, \rho)$, and $(\log y_1, \log y_2) = (e_1, e_2)$ being bivariate normal. The asymptotic efficiency of the marginal estimate relative to the joint estimate is equal to $7(7 - 4\rho^2)/(49 - 8\rho^2 + 4\rho^2)$ for $\hat{\alpha}$, and $(2 - \rho^2)$ for σ . As ρ^2 approaches 1, the asymptotic relative efficiency tends to $7/15 \approx 0.47$ for the λ parameters and $1/2 = 0.50$ for the σ parameters. There is no improvement in estimating the β parameters in this case.

In general, the information matrix of the model parameters, including the transformation power, depends on the model in a rather complicated fashion but the comparison of statistical efficiency can be made case by case. Under the special case of a simple logarithmic model, it can be shown that the efficiency gain from the joint method in estimating the transformation parameters can be quite noticeable when the correlation between the transformed responses is significant. The efficiency gain is negligible for percentile curve estimation around the median but becomes more pronounced for more extreme percentiles. A simulation study in section “Correlated Response Variables” of^[20] demonstrated this general pattern.

AN EXAMPLE

Blood pressure is one of the important health indicators for adults. In developed countries, hypertension affects one in four human subjects. Screening of blood pressure is routinely done.

Since blood is carried from the heart to all of the body's tissue and organs in vessels called arteries, blood pressure is the force of the blood pushing against the walls of those arteries. Blood pressure is at its greatest when the heart contracts and is pumping the blood. This is called systolic pressure. When the heart is at rest, in between beats, blood pressure falls. This is the diastolic pressure. It is well known that the systolic and diastolic pressure readings are quite highly correlated. In addition, there is a higher chance for older people to suffer from high blood pressure.

The example used in^[20] is based on data from 4695 male adults (from 30–80 years old) from the 1998 Health Survey of England (<http://www.data-archive.ac.uk>). The authors use their systolic and diastolic pressures to construct percentile charts as a tool to understand blood pressure changes in the general male population (including

Fig. 2 Percentile curves for the blood pressure of English male adults. Solid curves are obtained from the marginal method, and the dashed ones are from the joint method

those with hypertension). A joint power transformation to normality can be considered for those two correlated blood pressure readings.

Using cubic polynomials as percentile curves, the marginal method gave a transformation power $\hat{a}_1 = -0.55$ (with standard error, $SE = 0.12$) for the systolic pressure and $\hat{a}_2 = 0.40$ (with $SE = 0.09$) for the other. The joint method however led to $\hat{a}_1 = -0.37$ ($SE = 0.10$) and $\hat{a}_2 = 0.60$ ($SE = 0.07$). The correlation between the transformed variables is about 0.7 in this case. We see that the λ estimates from the two methods are more than two SEs apart. The resulting percentile charts (displaying curves at 1%, 5%, 10%, 25%, 50%, 75%, 90%, 95%, 99% levels) from both methods are shown in Fig. 2. Note that for extreme quantiles, the joint method produces slightly lower curves with the maximum difference of 2 mm of mercury. A medical doctor can use the curves to say that a male patient at age of 60 with a diastolic blood pressure reading of 107 is at the 95 percentile of the general male population.

CONCLUSION

Age-specific percentile curves can be computed one at a time even when there are two or more related variables of concern. For the Box-Cox transformation (towards normality), we have the option of the joint normal

likelihood method in addition to the marginal method. Albeit these two methods often produce similar charts, the joint method can lead to a noticeable efficiency gain for extreme quantile estimation, especially when the correlation among the variables is greater than half. In addition, there is an added diagnostic value for using both the marginal and the joint methods for the same problem. A substantial difference in the resulting percentile curves is indicative of severe model inadequacy or failure of power transformations to the intended normality. In such cases, other methods such as those reviewed earlier in the paper may be called for.

The comparison here between the joint and the marginal estimation was limited to the use of the Box-Cox transformation. However, our findings may serve as a reference point for users who may be interested in studying joint percentile curve estimation using a more flexible or advanced statistical method.

Recently, it has been shown in^[27] that conditional growth charts are valuable in screening current status based on individual history. The regression quantile approach can be naturally extended to percentile charts conditional on past measurements or some other covariates. Bivariate and multivariate quantile contours can be constructed using a method recently developed in Ref. [22], and research in this direction might accelerate in the future.

Abstract

This entry provides general considerations for the validation of diagnostic medical devices whose results have direct or indirect potential to “personalize” patient care. In particular, the clinical validation of companion diagnostic devices and corresponding therapeutic products, risk prediction devices, and monitoring devices are discussed. In addition, the often neglected topic of analytically validating the biomarker measurement(s) made by a diagnostic device, including measurement accuracy and reproducibility is discussed.

Keywords: Precision medicine; Biomarker; Measurement performance; Clinical validation; Treatment selection; Risk prediction; Monitoring; Diagnostic device.

INTRODUCTION

“Personalized medicine” or “precision medicine” has been described in grand terms as treating “the right patient with the right drug at the right dose at the right time.”^[1] The National Academy of Sciences defines precision medicine as “the use of genomic, epigenomic exposure and other data to define individual patterns of disease, potentially leading to better individual treatment.”^[2] The fervor over the potential of precision medicine to optimize patient care is warranted, due to not only advances in high-throughput molecular profiling (e.g., next generation genomic sequencing) but also to corresponding regulatory initiatives.^[3] Operationally, medical care is “personalized” by applying a medical model to stratify patients into different subpopulations, in efforts to tailor or “individualize” patient care.^[1,2] To define the patient strata, a predictive model can be used, for example, likely response

or adverse reaction to a treatment, risk of incident disease in a non-diseased subject, or risk of hospitalization, disease progression, relapse, or recurrence in a diseased patient.^[4] Predictions of future event (risk predictions), treatment response, or treatment adverse reaction are typically based on one or more biomarkers,^[5] measured or detected by diagnostic devices (tests) or by some other measurement procedure.

An early example of personalized medicine is the breast cancer treatment *Trastuzumab* (Herceptin), indicated for patients whose breast tumor tissue overexpresses human epidermal growth factor receptor 2 (HER-2). In 1998, the Food and Drug Administration (FDA) approved Herceptin together with an immunohistochemical (IHC) In Vitro diagnostic (IVD) HercepTest™ for measuring HER-2 expression.^[6] HercepTest™ is considered one of the first in vitro “companion diagnostic” devices, that is, an IVD test that is essential for the safe and effective use

of the corresponding therapeutic product.^[7] Since the FDA approvals of Herceptin and HercepTest™, interest in identifying candidate biomarkers in personalized medicine has grown tremendously. Other successful examples of therapeutic products with accompanying IVD companion diagnostics include Venclexta® (venetoclax; AbbVie Inc.) and Vysis Cll Fish Probe kit (Abbott Molecular Inc.), Erbitux (cetuximab; ImClone Systems) and *therascreen* KRAS RGQ PCR kit (Qiagen Manchester Ltd.).^[6] FDA has released draft guidance on principles for codevelopment of an in vitro companion diagnostic device (CDx) with a therapeutic product.^[8]

While the term “precision medicine” or “personalized medicine” is often interpreted as selecting the treatment best suited for an individual patient, the term is used more broadly in this entry. Specifically, personalized medicine is referred to as encompassing genetic and other available information that could be used to influence individual medical decision-making, including safety or effectiveness of a treatment or intervention, risk of incident disease, prognosis of a diseased patient either untreated or on a standard treatment, and the value of a clinically meaningful biomarker monitored over time.

Biomarkers can be classified according to their intended use (IU). Predictive biomarkers are used to predict treatment response or to inform treatment selection, usually based on a differential treatment effect between the biomarker-negative and biomarker-positive populations. Ideally, the biomarker by treatment interaction is nearly qualitative, which may occur when the biomarker is the target of the treatment. An in vitro companion diagnostic device (or test) is an IVD device and could be essential for the safe and effective use of a corresponding therapeutic product to identify: 1) patients who are most likely/likely to benefit from a particular therapeutic product or patients who are eligible for a particular therapeutic product; 2) patients likely to be at increased risk of serious adverse reactions as a result of treatment with a particular therapeutic product; and 3) response to treatment for the purpose of adjusting treatment to achieve improved safety or effectiveness.^[7] Based on how it is validated clinically, there are two main types of indications for use or claims based for a companion diagnostic device^[7] which detects or measures predictive biomarker, namely, predictive test and selection test. Predictive tests are clinically validated by demonstrating the differential treatment effect between marker-positive and marker-negative patients defined by the device by treatment interaction.^[8] This type of clinical evidence is generally demonstrated from the clinical trials in which both test-positive and test-negative subjects are enrolled. Selection tests are clinically validated by demonstrating the treatment effect in marker-positive (or marker-negative) patients defined by the device. Often for selection tests, only test-positive (or test-negative) subjects are selected for enrollment in a clinical trial. For a selection test, if the treatment efficacy

trial demonstrates adequate safety and effectiveness of the therapeutic product within the population selected by the test, then the test is considered to be “clinically validated”. In that, it selected a population that benefits from therapy.^[7]

Prognostic biomarkers are used for predicting a future outcome for patients either untreated or on a standard of care therapy. Many biomarkers, such as hormone-receptor status in breast cancer, are both prognostic and predictive. Many types of biomarkers exist, including proteins, nucleic acids, antibodies, and peptides. A biomarker can also be a collection of alterations, such as gene expression, proteomic, and metabolomic signatures. Biomarkers can be detected in the circulation (whole blood, serum, or plasma) or excretions or secretions (stool, urine, sputum, saliva, or nipple discharge) or can be tissue-derived such as formalin-fixed, paraffin-embedded biopsied tissue. Genetic biomarkers can be inherited, e.g., sequence variations in germ line DNA isolated from blood, or can be somatic, e.g., somatic DNA alterations in human cancer.

In this entry, we distinguish between the biomarker and the biomarker assay, i.e., the reagents, instruments, systems, apparatuses, or platforms used to measure or detect the biomarker, which may be referred to as the diagnostic device or test. To ensure that a new biomarker introduced into clinical practice will appropriately direct patient management, the diagnostic device measuring/detecting the biomarker should undergo rigorous evaluation, including analytical and clinical validation, prior to its incorporation into patient management. Here, validation of a candidate device refers to an evaluation of its analytical and clinical performance in the study independent from its development. A candidate device is said to be validated if it meets a set of analytical and clinical performance goals (usually with statistical significance). The performance goals are chosen such that, if met, and the device if used per instructions for use, should provide clinically significant results in a significant portion of its target population. Broadly, validation of a diagnostic device includes an assessment of its safety and effectiveness and whether its probable benefits outweigh any probable risks.

As discussed above, the IU of predictive, prognostic, and monitoring biomarker devices are quite different, implying different requirements for clinical validation. In the section “Measurement Performance Validation of Diagnostic Devices,” the validation of the measurement(s) made by diagnostic devices, e.g., their accuracy and reproducibility is discussed in general. In the sections “Treatment Selection: Clinical Validation of a Companion Diagnostic and the Corresponding Therapeutic Product” and “Risk Prediction”, the clinical validation of diagnostic devices for treatment selection, risk prediction, and monitoring are specifically discussed. In section the “Conclusion,” some concluding remarks are provided.

MEASUREMENT PERFORMANCE VALIDATION OF DIAGNOSTIC DEVICES

Results from a diagnostic device are often essential in patient treatment and management. Inadequate performance of a diagnostic device could have severe therapeutic consequences. For example, for a CDx, erroneous diagnostic device results could lead to withholding appropriate therapy or to administering inappropriate therapy. When a new biomarker is being developed, it is important to validate measurement performance of the assay detecting the biomarker. A device's measurement performance can be impacted by preanalytical, analytical, and postanalytical factors. Preanalytical factors are related to specimen collection as well as handling and storage. Postanalytical factors are related to data entry and calculations, interpretation of the results, data transfer and the methods used to report the results, etc. Analytical factors are described by characteristics, such as measurement bias, measurement precision (repeatability, intermediate precision, and reproducibility), limits of detection, limits of blank, stability (of the device and sample), interferences, sample commutability, and others. The definitions of the terminology in this section and other terms are found in literatures.^[9–13]

The types of analytical validation studies required for a diagnostic device depend on the device's IU, but two aspects of measurement validation commonly assessed across most types of tests are accuracy and precision. Accuracy is the closeness of the agreement between the result of a measurement and a true value of the measurand.^[9] Precision is the closeness of agreement between replicate measurements on the same object (e.g., sample) under specified testing conditions. The specified testing conditions can be repeatability conditions—replicate measurements on the same or similar objects under the same or similar conditions; reproducibility conditions—replicate measurements on the same or similar objects using different operating conditions; or some other set of intermediate conditions. Some factors which may impact the device's precision are reagent lot, operator, instrument, day, device run, replicate, and testing site. When the device results are visually interpreted by readers, it is important to evaluate reader-to-reader variability. For example, for IHC tests, site, lot, instrument, operator, day, run, replicate, and readers are often considered in the precision study. For continuous measurements, imprecision is typically expressed as a standard deviation and a percent coefficient of variation. For categorical or binary measurements, precision is typically expressed as percentage agreement among the replicates.

The device should be “locked down” with regard to its design parameters and fully prespecified with regard to its indications for use and IU before the initiation of measurement validation studies or trials, although carefully designed adaptive design that allows intratrial cutoff

alterations may be acceptable in some situations.^[7] For many diagnostic devices in precision medicine, the final output is a categorical result that classifies subjects into two or more groups (e.g., mutation present or absent). Devices with final categorical results often have an underlying continuous measurement that is then categorized based on a prespecified cutoff(s). The cutoff value is the point for defining test-positive or test-negative results. For companion diagnostic tests, subjects with positive test results are those who are suitable for a treatment, choose the appropriate dose, or make other clinical decisions. Prespecified cutoff values are essential for the validation of a diagnostic device in a clinical trial, since changing the cutoff values implies re-classifying the patient groups. It is recognized that the optimal cutoff may be unknown prior to the availability of clinical data. In such cases, an independent clinical trial confirming the results with the predetermined cutoff, or an adaptive design that allows intratrial cutoff alterations, would be necessary to validate the device and corresponding targeted therapy.^[7]

TREATMENT SELECTION: CLINICAL VALIDATION OF A COMPANION DIAGNOSTIC AND THE CORRESPONDING THERAPEUTIC PRODUCT

When a clinical trial is properly designed to establish the efficacy and safety of a therapeutic product in a biomarker-defined patient population, the results of the clinical trial are also used to establish the clinical validity of the CDx which measures or detects the biomarker(s). There are a variety of clinical trial designs that may be used to validate a CDx and the corresponding therapeutic product. The appropriate clinical trial design depends on the IU of device, proposed objectives, hypothesis of interest, and what has already been established during the development stage of the device and therapeutic product. Biomarker-stratified and targeted designs are the two most commonly used clinical trial designs that evaluate an investigational therapy along with a CDx (Fig. 1); however, other designs could also be considered appropriate. Without loss of generality, in this entry, we assume that the biomarker-positive patients are the targeted patients of the therapeutic product and patients in a clinical trial will be randomized to either therapeutic treatment or control arms.

The success of a clinical trial depends on many factors including, but not limited to, the following: 1) the characteristics of the biomarker; 2) the corresponding therapeutic product's safety and efficacy; 3) the ability of the CDx to predict differential effects of the treatment on outcome or the ability of the CDx to properly select patients who respond well to the treatment; and 4) the device measurement performance as discussed in the section “Measurement Performance Validation of Diagnostic Devices.”

Fig. 1 Clinical trial designs. Trial A is called biomarker-stratified design^[4,14] used to evaluate treatment effects, biomarker effects, and their interaction, by stratifying randomization based on biomarker status, as determined by a companion diagnostic. Trial B is called targeted design^[4,14] used to evaluate treatment effects in a targeted population of biomarker-positive patients. Note: + = biomarker-positive; - = biomarker-negative; R = randomize. Treatment A is the experimental arm and treatment B is the control arm, typically standard of care or placebo

Biomarker-Stratified Design

In the clinical trial design depicted in Fig. 1A, both biomarker-positive and at least a proportion of biomarker-negatives are enrolled. This design is useful as it is desirable to obtain information about the safety and efficacy of the therapeutic product for both marker-positive and marker-negative patients in the clinical trial to ascertain the appropriateness of restricting the therapy to the biomarker-positive group. This approach may be particularly valuable when the biological plausibility or medical relevance of the biomarker is not well understood. When biomarker positivity (defined as the probability of patients being biomarker-positive) population is not low (e.g., >10%), an all-comers design could be used, i.e., all eligible subjects, regardless of biomarker status, are enrolled into the trial. When biomarker positivity is low, marker-positive patients may be enriched, as an all-comers trial design would require a large sample size. Specifically, all eligible biomarker-positive patients and a randomly selected proportion of eligible biomarker-negative patients will be enrolled to the trial. Therefore, biomarker-positive patients are enriched in the study population, relative to an all-comers trial.

The primary objective of the clinical trial under this design is to determine whether the biomarker of interest is truly a predictive biomarker. The most convincing evidence would be a clinically and statistically significant interaction between the treatment and the biomarker status defined by the device (denoted as γ). Therefore, the primary analysis for biomarker-stratified design is treatment by device interaction (biomarker predictive value), i.e., the hypothesis of interest:

$$H_0: \gamma \leq \delta \text{ vs. } H_a: \gamma > \delta \quad (1)$$

where δ is a predefined clinically meaningful value.

In addition to the predictive value, a biomarker-stratified design is useful for assessing a marker's main effect (marker prognostic value), drug efficacy in biomarker-positive patients (denoted as γ_1), drug efficacy in biomarker-negative patients, and overall drug efficacy

which can also be the primary analysis (denoted as μ). Note that under the marker-positive patients are enriched, if the drug efficacy is significantly different between biomarker-positive and biomarker-negative patients; the estimate of overall drug efficacy from such a trial will usually need to be adjusted for the enrichment in order to make a proper inference about the device IU population. When assessing overall drug efficacy, one also needs to determine whether μ is driven by the drug effect in biomarker-positive patients defined by the device.

Targeted Design

In the design shown in Fig. 1B, only biomarker-positive subjects are enrolled into the clinical trial. This design could be used under certain circumstances, e.g., when biological plausibility or medical relevance of the biomarker is well understood or if there is persuasive evidence indicating harm or lack of efficacy in the biomarker-negative subpopulation.^[7] Unlike the biomarker-stratified design, with this design, the predictive value of the device (and biomarker) cannot be determined because there is no information on the treatment efficacy in the biomarker-negative population. Likewise, there is no information about the prognostic value of the device. Under this design, the primary objective of the trial is to evaluate the therapeutic product efficacy in patients defined as biomarker positive by the CDx and it is not to validate the predictive value of the CDx, i.e., the hypothesis of interest:

$$H_0: \gamma_1 \leq \delta_1 \text{ vs. } H_a: \gamma_1 > \delta_1 \quad (2)$$

where δ_1 is a predefined clinically meaningful value and γ_1 is the treatment effect in device-positive patients. Several successful examples of therapeutic products with an accompanying IVD companion diagnostic including Gleevec (Imatinib; Novartis), DAKO C-KIT pharmDx (Dako North America, Inc.), Erbitux (cetuximab; ImClone Systems), and *therascreen* KRAS RGQ PCR kit (Qiagen Manchester Ltd.) were validated using a targeted design.^[6]

Bridging Study

It is less complicated when the biomarker status of patients enrolled in to the clinical trial is defined by a well-characterized investigational device, e.g., a device with analytical characteristics of the proposed “to be marketed CDx,” so that appropriate clinical and analytical validation studies apply directly to the CDx and the corresponding therapeutic product. However, for various reasons, this may be difficult or impractical to meet. Instead of the investigational CDx, a prototype of the CDx, a clinical trial assay (CTA), may be used to determine patient biomarker status in the clinical trial. One reason that the CTA might be used is that the investigational CDx is not available at the time of the clinical trial, and the CTA is available and used for patient enrollment in the trial and for the analysis of samples. In such cases, a bridging study, which is a concordance study of the proposed CDx and the CTA using the samples from the CTA-drug pivotal clinical trial, would be warranted to evaluate the clinical utility of the proposed CDx for the corresponding therapeutic product. The statistical issues, study design, and data analysis for the bridging study are discussed in detail in literature.^[15]

Prescreening Bias

When the prevalence of biomarker positivity is low, a large number of patients will usually need to be screened by the investigational CDx in order to enroll a sufficient number of biomarker-positive patients to properly power the clinical trial. In order to accelerate the enrollment process, patients could be prescreened first by prescreening tests and the results “confirmed” by the investigational CDx. Prescreening could be performed by one or several tests which could be a local developed test(s) or a prototype CDx. Prescreening may result in a biased clinical trial population that does not represent the device/therapeutic product IU population in real-world testing^[16] and consequently could lead to biased estimate of device clinical performance or drug effect.

We use the targeted design as an example to illustrate the issue. If patients are prescreened by a prescreening test, only patients who are prescreened-positive and investigational CDx-positive (denoted as double positives) will be enrolled to the trial. Patients who are prescreened negative will not be tested by the investigational CDx and will not be enrolled to the trial. Some of these patients could have been investigational CDx positive and may have been eligible to be enrolled into the trial if there were no prescreening. Thus, the trial could have been subject to selection bias due to prescreening (also called prescreening bias) because the study population is double positive which is different from the drug IU population, i.e., investigational CDx-positive patients. Prescreen negatives might represent populations with characteristics that make it more difficult

to test, etc., and so the investigational CDx would not be assessed under those conditions.

A statistical model may be used to correct a prescreening bias if the following information is available: the drug efficacy in prescreening-negative and investigational CDx-positive patients, the concordance between the prescreening test and the investigational CDx, and the percentage of investigational CDx positivity, etc. However, such information is often not available. Therefore, prescreening can create technical problems for sponsors attempting to evaluate a novel therapeutic product's safety and efficacy in its IU population as well as for CDx manufacturers attempting to provide an unbiased estimation of the investigational CDx performance. Thus, planning to enroll subjects into a trial based on the confirmation of a local test result can be problematic. When prescreening is unavoidable, it may useful to be aware of the potential bias, take precautionary steps to evaluate whether the expected marker positivity may be skewed by prescreening, and develop approaches to adequately address potential selection bias.

Adaptive Signature

The increasing awareness of heterogeneity in treatment effect has motivated clinical trial designs that prospectively allow for demonstration of treatment efficacy in a subpopulation of patients. If a promising subpopulation is available at the trial design stage, this knowledge can be used to plan a prespecified subgroup analysis in a traditional broad eligibility trial or to restrict enrollment in a targeted trial, depending on how confident the investigator is about the subpopulation. Such a well-defined subpopulation is often unavailable in the design stage; instead, the investigator may only have a preliminary idea that a collection of baseline covariates (biomarkers) could be useful in identifying a sensitive subpopulation. In that case, a target subpopulation can be developed at the end of a broad eligibility trial under an adaptive signature design or at an interim analysis (with the possibility of restricting subsequent enrollment) under an adaptive enrichment design.^[17] The various designs have been discussed and compared by Chen et al.^[18]

There has also been intensive research on estimating optimal treatment regimens from clinical trials or observational data. A treatment regimen may involve a single treatment decision based on baseline characteristics^[19] or a sequence of treatment decisions based on time-dependent covariates.^[20] These methods tend to be exploratory in nature and have to be applied in a confirmatory fashion.

RISK PREDICTION

Absolute risk is the cumulative probability that a patient experiences an adverse health event or clinical outcome of

interest by a particular time in the future.^[21] For example, healthy people may be assessed for their lifetime risk of developing breast cancer^[22] or experiencing a cardiovascular event,^[23] according to risk factors for these events. Patients with disease may be assessed for prognosis, e.g., risk of hospitalization, disease progression, mortality, relapse, or recurrence. Risk is an important factor in the patient's medical management and in fact is often the basis by which accredited organizations form guidelines on the medical management, treatment, or screening intervals of specific populations. For example, during chemotherapy treatment of patients with breast cancer, prophylactic use of granulocyte colony-stimulating factor has been recommended if the risk of febrile neutropenia is greater than 20%.^[24]

The utility of a risk prediction varies with the application. In many clinical settings, risk informs medical care professionals by helping them to determine the frequency with which patients should be screened for an event of interest. A risk prediction may also assist physicians in the decision to prescribe or not to prescribe an intervention or treatment designed to mitigate the risk.

Predictive models are increasingly being developed in attempts to estimate the risk of an event from a model that combines information on predictor variables, including patient characteristics (e.g., age, body mass index, and disease stage) and biomarkers (biological characteristics associated with the likelihood of disease). Unfortunately, most prediction models do not successfully proceed from bench (research) to bedside (clinical practice). A common reason for failure is attempting to estimate the model performance on the same dataset on which it was developed. This re-substitution can result in huge performance biases, leading to an overly high expectation of success in an independent validation study. This bias can be mitigated with rigorous cross-validation of all model development steps, especially selection of the predictor variables from potential candidates.^[25]

Another reason that many predictive models fail is poor experimental design of the development study. Examining a biomarker for association with a clinical outcome on a retrospectively collected, archived set of specimens conveniently available from disparate sources, can often result in the association being confounded by biomarker assay measurement variation due to preanalytical and analytical factors. Studies of such convenience samples are generally discouraged to mitigate the confounding of biomarker associations with unmeasured variables related to the availability of the samples. One way to ensure that uniform policies are in place for specimen collection, archival, and centralized processing is to obtain specimens from one or more adequate, well-conducted, well-controlled studies of a population appropriate for the prediction goal.^[26]

Similarly, when designing a prospective developmental study, application of good experimental design principles

is also essential. A prospectively designed development study would ideally be balanced on all controllable confounding factors such as those known to produce technical variations in the measurements from biomarker assays.

In summary, planning the intention and design in predictive model development study is as important as validating the model itself. Careful annotation of research steps can be extremely helpful to ensure that the research is reproducible.

A fully developed risk prediction model may be embedded in a medical device that is being evaluated by a regulatory authority for premarket approval. To support approval, the risk prediction device would generally be validated with data, independent of developmental data set. To ensure that the performance of the device in the validation study is generalizable to new subjects, statistical rigor necessitates that the device is “locked down” with regard to its design parameters. It is also important to ensure that subjects enrolled in the study are fully prespecified with regard to its indications for use and of the device IU population, and that the use of the device in the study is consistent with its instructions for use.

The successful validation strategies for some prognostic tests have been reviewed for statistical lessons learned.^[27]

If a risk prediction model reports a risk category (e.g., low, moderate, or high risk), differences in risk between categories can be helpful in assessing clinical significance of the model and can be estimated from Kaplan–Meier curves for the categories (assuming a prospective all-comers study design). Comparing risk categories using relative risks or hazard ratios are generally insufficient for assessing clinical significance and making decisions on patient management. For example, a relative risk of three could indicate an increase in risk from 0.1% to 0.3% or from 8% to 24%. Depending on the medical setting, the former risk difference of 0.2% could be considered clinically insignificant, while the latter risk difference of 16% could be considered clinically important, suggesting that absolute risk and absolute risk differences are generally more clinically useful to consider than just relative risk. Similarly, measures of discrimination such as sensitivity, specificity, and odds ratio are often less useful for assessing clinical significance of the risk categorization than are differences in absolute risk between the categories.

If a model reports a probabilistic value $r(x)$ of the risk for a subject based on predictor value x , then the clinical usefulness of this risk prediction can be evaluated for how well it is calibrated to the actual risk $\pi(x)$ for that subject. If $r(x)$ is not well-calibrated, then a particular subject may be mismanaged according to guidelines for management predicated on risk. The Hosmer–Lemeshow goodness-of-fit test is popular for evaluating whether probabilistic risk predictions are well-calibrated with actual risk based on grouping subjects according to their risk prediction.^[21]

In other evaluation risk prediction, predictors (or the risk prediction itself) may be included in a regression model such as a logistic regression of disease status or a Cox regression of time to disease onset. Such models can be useful for assessing the proportion of variation in risk that is explained by the predictor.^[21,28] Such models can also be used to obtain the predictiveness curve, a plot of the distribution of risk among subjects based on the particular model.^[29]

Discrimination ability or classification accuracy of the risk prediction can be assessed overall with the receiver operating characteristic (ROC) plot of pairs of sensitivity and specificity conferred by cutoffs in the risk prediction. Interestingly, models that are perfectly calibrated for risk may not necessarily achieve perfect discrimination (i.e., area under the ROC curve of 1).^[21]

To be clinically useful, predictive models ought to provide some advantage or added value in the assessment of risk compared with the armamentarium of risk factors that are often already available and is in the routine clinical use. The incremental value of a risk prediction can be assessed with a multivariable logistic or Cox regression analysis that includes known risk factors in addition to the biomarker risk prediction being evaluated. Ultimately, the clinical value of a risk prediction model may need to be assessed according to assumed clinical consequence of misclassifying risk or with a clinical validity study to evaluate whether use of the model for patient management leads to improved clinical outcomes.

CONCLUSION

This entry discusses three major IU of diagnostic devices for precision medicine, namely, treatment selection, risk prediction, and disease or treatment monitoring. General considerations for clinical validations for each IU are discussed. This entry does not discuss other IU of precision medicine, e.g., complementary diagnostics. Biomarkers play a critical role in precision medicine, with applications including prognosis, monitoring, and selection of targeted therapies. Once a candidate assay detecting a marker has been developed, the devices detecting/measuring biomarker must be studied to determine if it has clinical validity. Observation of apparent clinical validity needs to be reproduced in an independent clinical trial in order to confirm clinical validity.

Pharmaceutical Development: Statistical Designs

Annpey Pong

Abstract

A pharmaceutical development process consists of non-clinical (e.g., assay and process validation and stability testing), pre-clinical (e.g., animal and bioavailability bioequivalence studies), and clinical (e.g., phases 1–3 clinical trials) development. In this entry, various statistical designs that are commonly considered for achieving desired good drug characteristics as described in the United States Pharmacopeia and National Formulary (USP/NF) at various stages are reviewed.

Keywords: Pharmaceutical development process; Quality by design; Assay validation; Process validation; Stability analysis; Adaptive design methods in clinical trials.

INTRODUCTION

The pharmaceutical development process, involving drug discovery, formulation, laboratory development, animal studies, clinical development, and regulatory registration, is a continual, length, and costly process. Essentially, a pharmaceutical development process consists of different phases of development, including non-clinical development (e.g., assay development/validation in laboratory development, manufacturing process validation, and stability testing and analysis), pre-clinical development (e.g., animal studies and bioavailability/bioequivalence studies), and clinical development (e.g., phase 1–3 clinical development).^[1] These phases may occur in sequential order or be overlapped during development process. At different phases of pharmaceutical development, valid statistical designs are usually employed to ensure that the drug product possesses good drug characteristics such as identity, strength, quality, purity, safety, efficacy, and stability before and post-approval of the drug product.

In this entry, we will not only introduce the concept of quality by design suggested by the FDA, but also provide an overview of statistical designs that are commonly employed at different stages of a pharmaceutical development.

QUALITY BY DESIGN (QbD)

In many practical cases, the pharmaceutical manufacturing process is not only unable to meet pre-specified quality standard, but also inability to predict effects scale-up on final product. Quality by design (QbD) is a concept that quality could be planned, and that most quality crises and

problems relate to the way in which quality was planned. The FDA has implemented the concepts of QbD into its pre-market processes.^[2] The focus of this concept is that quality should be built into a product with an understanding of the product and process by which it is developed and manufactured along with a knowledge of the risks involved in manufacturing the product and how best to mitigate those risks. Winkle provides a comprehensive comparison of traditional approach with the systematic QbD approach (see [Table 1](#)).^[3]

The use of quality by design cannot only reduce number of manufacturing supplements required for post market changes and at the same time, allow for implementation of new technology to improve manufacturing without regulatory scrutiny. From the perspectives of FDA, the implementation of QbD will not only enhance scientific foundation for review, but also provides better coordination across review, compliance and inspection divisions within the FDA. Additionally it not only improves information in regulatory submissions and quality of review, but also provides for better consistency and for more flexibility in decision making.

NONCLINICAL APPLICATION

Assay Validation

The major objective of the validation of an assay method is to ensure that the assay method can produce unbiased and precise assay results for the active ingredient of a compound. The USP/NF indicates that the assay method needs to be validated in terms of the primary

Table 1 A Comparison between Traditional Approach and QbD Systematic Approach

Aspects	Traditional	Quality by Design
Pharmaceutical Development	Empirical; Univariate experiments	Systematic; Multivariate experiments
Manufacturing Process	Fixed	Adjustable
Process Control	In-process testing for go/no-go; Offline analysis w/ slow Response	Process Analytical Technology utilized for feedback and feed forward at real time
Product Specification	Primary means of quality control; Based on batch data	Overall quality control strategy; Based on desired product performance (safety and efficacy)
Control Strategy	Based on intermediate and end product testing	Risk-based; Controls shifted upstream; Real-time release upstream
Lifecycle Management	Reactive to problems; Scale-up and post-approval changes	Continual improvement enabled within design space

validation parameters given in Table 2.^[4] To meet the USP/NF standards for each of these parameters, an appropriate statistical design is necessarily chosen to provide sound statistical inferences for these parameters and their variances. Several commonly employed designs in assay validation are briefly described below.

Randomized block design – This is the most commonly used design in assay validation. Suppose that there are J levels of potency (say [L, M, H] where L/M/H indicate low/median/high of the level of 100% of label claim) in a recovery study. Samples are assayed on different days with and/or without the same number of replicates (say 3 replicates). This design provides independent estimates of day-to-day variability and within-day variability.

Latin square type of design – In the randomized block design, assays of different levels on the same day are usually performed in sequential order, which may introduce bias due to testing order. To avoid the bias that may be introduced by testing order, a Latin square type of design is used to balance the potential bias. In other words, the number of days should be equal to the number of levels. The Latin square design is then applied to the test sequence of the levels of potency.

Incomplete block design – In practice, the number of assays performed on each day may not be able to cover all

the levels of potency under study due to limited resources available. In addition, in some cases, the assay can only be conducted on a certain number of days, which are fewer than the number of levels of potency. In these situations, an incomplete block design may be used to randomize test sequences on each day.

Process Validation

A manufacturing process is a continuous process that involves a number of critical stages for quality assurance. At each critical stage, problems may occur during the process. Thus, process validation is essential not only to ensure that the process does what it purports to do, but also to ensure that the drug product will conform to USP/NF specifications of good drug characteristics.

Regulatory requirement – In its recent guidance on process validation, FDA underlines the concept of QbD in process validation to continue benefiting from knowledge gained, and continually improve throughout the process lifecycle. For a prospective validation, FDA requires that at least three batches be evaluated. A validation design that clearly outlines sampling plan, testing plan, and acceptance criteria for validation are briefly described below.

Sampling plan, testing plan, and acceptance criteria – The validation of a manufacturing process requires satisfactory results at each critical stage for three batches. For each batch, sampling plan and testing procedures may be different from stage to stage. Acceptance limits for the validation of a manufacturing process are usually designed to be more stringent to assure that the final product will pass USP/NF specifications. Acceptance limits are a set of sample statistics from which a confidence interval for a given parameter is constructed to meet a pre-specified lower probability bound for passing a particular USP test.

Scale-up

Scale-up program plays an important role to scale up a laboratory batch to a commercial (production) batch. The purpose of a scale-up program is not only to identify, evaluate, and optimize critical formulation and/or manufacturing process factors of the drug product but also to maximize or minimize excipient ranges. A successful scale-up program can result in an improvement in formulation/process or at least a recommendation on a revised procedure for formulation/process of the drug product. Some commonly employed designs in scale-up experiments are briefly described below.

Factorial design – A full factorial design is a design that consists of all possible different combinations of one level from each factor. If there are l_k levels for the k th factor X_k , the corresponding full factorial design is called a general $l_1 l_2 \dots l_K$ factorial design. For example, when $l_i=2$ for all i , the general factorial design is called a 2^K factorial design. A full factorial design provides estimates not only for main effects but also for interactions with maximum precision. The main effects and interaction effects can easily be obtained using a table of contrast coefficients and/or Yate's algorithm.^[5–6]

Fractional factorial design – This design consists of a fraction of a full factorial experiment. For example, a $(\frac{1}{2})^P$ fraction of a 2^K factorial design is called a 2^{K-P} fractional factorial design. When $P=1$, a full factorial design reduces to a one-half factorial design. For a 2^{4-1} fractional factorial design, the eight observations cannot provide independent estimates for the 16 effects alone but for some confounding effects, such as the sum of a main effect and a three-factor interaction that are confounded with each other. In practice, however, the three-factor or higher-factor interactions are usually negligible. In this case, a fractional factorial design is useful in estimating the main effects. In practice, a fractional factorial design is useful when there are many factors to be studied because it is almost impossible to perform a full factorial design even at two levels.

Central composite design – This design is a full factorial design or a fractional factorial design augmented by a $\pm \alpha$ level at each of the K factors and n central points. It consists of 1 center point, 8 points on the cube (a 2^3 factorial arrangement), and 6 star points (Table 3). It should be noted that a central composite design with $K=2$, $\alpha=1$, and $n=1$ reduces to a 3^2 factorial design. For a full 2^K factorial design, although the design provides independent estimates for the 2^K-1 effects, it does not give an estimate of the experimental error unless some runs are repeated. Unlike the full 2^K factorial design, the central composite design provides an estimate of the experimental error. The experimental error is usually estimated based on n observations at the central point.

Table 3 Central Composite Design for $K=3$ and $n=1$

Run	X_1	X_2	X_3
1	–1	–1	–1
2	1	–1	–1
3	–1	1	–1
4	1	1	–1
5	–1	–1	1
6	1	–1	1
7	–1	1	1
8	1	1	1
9	0	0	0
10	α	0	0
11	$-\alpha$	0	0
12	0	α	0
13	0	$-\alpha$	0
14	0	0	α
15	0	0	$-\alpha$

Stability Analysis

For study design and sample selection criteria, the ICH Q5C guideline recommends that a bracketing design or a matrixing design be used.^[7–12] In other words, samples for the stability program can be selected on the basis of a matrixing and/or bracketing design.

A bracketing design is a design that only samples on the extremes of certain design factors which are tested at all-time points. Bracketing can be applied to studies with multiple strengths of identical or closely related formulation, or it can also be applied to studies with the same container closure system with the fill volume and/or the container size varied.

A matrixing design is a statistical design of a stability study that allows different fractions of samples to be tested at different sampling time points. Each subset of samples represents the stability of all samples at a given time point. Differences in the samples should be identified as covering different batches, different strengths, and different sizes of the same container closure system. A matrixing design should be balanced such that each combination of a factor is tested to the same extent over the duration of the studies. It should be noted that all samples should be tested at the last time point before the submission of application.

Storage Conditions – Stability studies are usually done at several different time points. In reality, there is no unique best design. The choice of design must use the fact that analyses will be done after data are collected. Nordbrock^[8] introduced several designs that are commonly considered in stability studies which are briefly described below.

Basic Matrix 2/3 on Time Design – A complete long-term study for one strength of a dosage form in one package has three batches, with all three tested every

3 months in the first year, every 6 months in the second year, and annually thereafter. The basic matrix 2/3 on time design has only two of the three batches tested at intermediate time points as presented in Table 4. If an analysis is to be done after 18 months for a registration application, the basic matrix 2/3 on time design can be modified by testing all batches at 18 months.

Matrix 2/3 on Time Design with Multiple Packages – The basic matrix 2/3 on time design is applied to each package in a balanced fashion, as presented in Table 5. *Balance* is defined as testing each batch twice at each intermediate time point, and each package twice at each intermediate time point.

Matrix 2/3 on Time Design with Multiple Packages and Multiple Strengths – Assuming there are three packages for each strength, the basic matrix 2/3 on time design can be applied to each of the 9 sub-batches in a balanced fashion (Table 6). In this design, each sub-batch is tested twice at each intermediate time point, each package is tested twice at each intermediate time point for each batch, each batch is tested six times at each intermediate time point, and each package is tested six times at each intermediate time point. If an analysis will be done after 18 months (e.g., for a registration application), this design can be modified by testing all batch-by-strength-by-package combinations at 18 months.

Matrix 1/3 on Time Design – A further reduction in the amount of testing is accomplished by reducing the testing

Table 4 Basic matrix 2/3 on time design

Batch	Test times (months)
A	0, 3, 9, 12, 24, 36
B	0, 3, 6, 12, 18, 36
C	0, 6, 9, 18, 24, 36

Table 5 Matrix 2/3 on Time Design with Multiple Packages

Batch	Package 1	Package 2	Package 3
A	T1	T2	T3
B	T2	T3	T1
C	T3	T1	T2

Table 6 Matrix 2/3 on time design with multiple packages and multiple strengths

Batch	Strength	Package 1	Package 2	Package 3
A	10	T1	T2	T3
A	20	T2	T3	T1
A	30	T3	T1	T2
B	10	T2	T3	T1
B	20	T3	T1	T2
B	30	T1	T2	T3
C	10	T3	T1	T2
C	20	T1	T2	T3
C	30	T2	T3	T1

Table 7 Basic Matrix 1/3 on Time Design

Batch	Test times (months)
A	0, 3, 12, 36
B	0, 6, 18, 36
C	0, 9, 24, 36

in each of the preceding designs from 2/3 to 1/3. For example, the basic 1/3 on time design has one of the three batches tested at each intermediate time point, as presented in Table 7.

Matrix on Batch-by-Strength-by-Package Combinations – For multiple strengths and multiple packages, one could also choose to test only on a portion of the batch-by-strength-by-package combinations. An example of matrix design on batch-by-strength-by-package combinations is presented in Table 8, with two packages selected for each of the 6 sub-batches, and where time is also matrixed by the factor 1/2. This design is approximately balanced.

Uniform Matrix Design – This design is for which the same time protocol is used for all combinations of the other design factors.^[12] The strategy is to delete certain times at 3-month, 6-month, 9-month, and 18-month; therefore testing is done only at 12, 24, and 36 months. This design has the advantages of eliminating time points that add little to reducing the variability of the slope of the regression line. The disadvantage is that if there are major problems with the stability, there is no early warning because early testing is not done. Further, it may not be possible to determine if the linear model is appropriate.

Comparison of Designs – Nordbrock compared designs based on the power approach.^[8] Other methods of comparing designs are given in Ju and Chow^[13] and Pong and Raghavarao,^[10] where the criterion is the precision for estimating shelf life. In addition, Nordbrock^[14] compared matrix designs to full designs using the probability of achieving the desired shelf life.

PRE-CLINICAL APPLICATION

Animal Studies

The primary focus of pre-clinical drug development is to evaluate the safety of the drug product through in vitro

Table 8 Matrix 1/2 on Time and Matrix on Batch-by-Strength-by-Package

Batch	Strength	Package 1	Package 2	Package 3
A	10	T1	T2	—
A	20	T2	—	T1
B	10	T2	—	T1
B	20	—	T1	T2
C	10	—	T1	T2
C	20	T1	T2	—

assays and animal studies. In vitro assay and animal testing are often considered as surrogate for human testing, under the assumption that they can be predictive of results in humans. Pre-clinical testing involves dose selection, toxicological testing for toxicity and carcinogenicity, and animal pharmacokinetics. For selection of an appropriate dose, dose-response studies are usually conducted to determine the effective dose such as the median effective dose ED_{50} in animals. The objective of toxicological testing in animal studies is to explore not only realistic safety extrapolation, but also to evaluate new methods to test for toxicity.

In pre-clinical development, the primary focus of toxicity testing in animals includes long-term carcinogenicity studies and reproductive toxicology studies. The major objective of the long-term carcinogenicity study is to identify those compounds that are probable human carcinogens, i.e., they have abilities to cause (i) an increased incidence of tumor types, (ii) an earlier appearance of tumors, and (iii) an increased multiplicity of tumors in individuals. The purpose of reproductive toxicology is to identify the effect of a xenobiotic on mammalian reproduction.

Gad and Weil^[15] indicated that there are four basic experimental designs that are commonly used in toxicology. These designs are completely randomized design, randomized block design, Latin square design, and nested design which are briefly described below.

Completely Randomized Design – This is the most commonly used design in toxicological testing. In this design, the treatments are completely assigned to the experimental units at random. The design imposes no restrictions on the allocation of treatments to the experimental units, although a balance on the number of experimental units used per treatment group is preferred. If there is evidence of heterogeneity on experimental units, it is suggested that blocking should be used to increase the design efficiency.

Randomized Block Design – In this design, the experimental units are allocated to blocks such that the experimental units within a block are relatively homogenous and the number of experimental units within a block is equal to the number of treatments being investigated. The treatments are assigned at random to the experimental units within each block.

Latin Square Design – A Latin square design is an extension of the randomized block design. Latin square design permits the investigator to assess treatment effects when a double-blocking restriction is used on the experimental units, controlling for two sources of variation. In the Latin square design, the number of row blocks, number of column blocks, and number of treatment groups are equal.

Nested Design – A nested design is a multi-factor experiment. As an example, suppose there are two factors (say factor A and Factor B). A nested design is a design in which levels of one factor (say Factor B) are hierarchically subsumed under (or nested within) levels of another

factor (say Factor A). Thus, it is not possible to assess the complete combination of A and B levels in a nested design.

Bioequivalence Studies

When a drug product is going off patent, pharmaceutical or generic companies may file an abbreviated new drug application (ANDA) for generic approval. Generic drug products are defined as drug products that are *identical* to a drug which is the subject of an approved NDA with regard to active ingredient(s), route of administration, dosage form, strength, and conditions of use. For approval of generic drug products, the FDA requires that evidence of average bioequivalence in drug absorption be provided through the conduct of bioavailability and bioequivalence studies. Bioequivalence assessment is considered as a surrogate for clinical evaluation of the therapeutic equivalence of drug products.

As indicated in the Federal Register (Vol. 42, No. 5, Sec. 320.26(b) and Sec. 320.27(b), 1977), a bioavailability study should be crossover in design, unless a parallel or other design is more appropriate for valid scientific reasons. A typical 2×2 crossover design can be expressed as (TR, RT), where TR is the first sequence of treatments and RT denotes the second sequence of treatments. Under the (TR, RT) design, qualified subjects who are randomly assigned to either sequence 1 (TR) or sequence 2 (RT), where TR represents the test product (T) first and then cross-over to receive the reference product (R) after a sufficient length of wash-out period. Similarly, RT sequence starts with product R first, and then product T after the wash-out period.

One of the limitations of the standard 2×2 crossover design is that it does not provide independent estimates of intra-subject variabilities since each subject receives the same treatment only once. Therefore, the following alternatives are often considered:

- Design 1: Balaam's design – i.e., (TT, RR, RT, TR);
- Design 2: Two-sequence, three-period dual design – i.e., (TTRR, RTT);
- Design 3: Four-period design with two sequences – i.e., (TRRT, RTTR);
- Design 4: Four-period design with four sequences – i.e., (TTRR, RRTT, TRTR, RTTR).

The above study designs are also referred to as higher-order crossover designs. A higher-order crossover design is defined as a design with the number of sequences or the number of periods greater than the number of treatments to be compared.

For comparing more than two drug products, a Williams' design is often considered. Williams' design is a variance stabilizing design. More information regarding the construction and good design characteristics of Williams' designs can be found in Chow and Liu.^[16]

CLINICAL APPLICATION

Selecting an appropriate statistical design is critical in clinical development during the process of drug development. Ideally an optimal design will account for considerations from different perspectives. The commonly statistical designs used in clinical application are summarized below.

Parallel versus Crossover

Crossover Design – A crossover design is a modified randomized block design in which each block receives more than one treatment at different dosing periods. Patients in each block receive different sequences of treatments. For a crossover design it is not necessary that the number of treatments in each sequence be greater than or equal to the number of treatments to be compared. We will refer to a crossover design as a $p \times q$ crossover design for p sequences of treatments administered at q different dosing periods. Basically a crossover design has the following advantages: (i) it allows a within-patient comparison between treatments, since each patient serves as his or her own control. (ii) It removes the inter-patient variability from the comparison between treatments. (iii) With a proper randomization of patients to the treatment sequences, it provides the best unbiased estimates for the differences between treatments.^[16–17]

Parallel Group Design – A parallel group design is a complete randomized design in which each patient receives one and only one treatment in a random fashion. Basically there are two types of parallel group design for comparative clinical trials, namely, group comparison (or parallel-group) designs and matched pairs parallel designs. The simplest group comparison parallel group design is the two-group parallel design which compares two treatments (e.g., a treatment group vs. a control group). The ICH E9 guideline “*Statistical Principles for Clinical Trials*” indicates that the parallel group design is the most common trial design for confirmatory trials.^[18]

Cluster Randomized Design

In clinical trials, the randomization units could be some social intact units such as family, school, worksites, athletic teams, hospitals, or communities. These social units are called *clusters*. The randomized design with clusters is referred to as cluster randomized design.

One of the major considerations for design and analysis of cluster randomized trials is the control of the intra-cluster and inter-cluster variations. Note that the subjects within the same cluster might share the same traits or have similar characteristics. In other words, the subjects within the same cluster are more similar than are those between clusters. One statistical measure to quantify this similarity is the intra-class correlation coefficient (ICC). If the intra-class correlation coefficient, denoted by ρ , is positive, then

the intra-cluster variation is smaller than the inter-cluster variation. The ICC plays a very important role in analysis of cluster randomized trials using subjects as the unit of inference.

Titration Design

For phase I safety and tolerance studies, Rodda et al.^[19] classify traditional designs as (i) rising single-dose design, (ii) rising single-dose crossover design, (iii) alternative-panel rising single-dose design, (iv) alternative-panel rising single-dose crossover design, (v) parallel-panel rising multiple-dose design, and (iv) alternative-panel rising multiple-dose design.^[20–21]

Phase I studies are usually conducted in young, healthy male volunteers. The purpose of phase I studies is to obtain initial appraisal of drug safety through the evaluation of vital signs, physical health, and adverse events and frequent assessments of hematology, blood chemistry, and urine samples.

In medical practice, if the study medicine is intended for cancer or some life-threatening diseases, it may not be ethical to conduct phase I safety and tolerance studies on normal volunteers due to potential toxic or fatal effects.

Adaptive Design

In February 2010, the FDA circulated a draft guidance on adaptive design clinical trials, which defines an adaptive design as a study that includes a prospectively planned opportunity for modification of one or more specified aspects of the study design and hypotheses based on analysis of (usually interim) data from subjects in the study.^[22] Analyses of the accumulating study data are performed at prospectively planned time points within the study, with or without formal statistical hypothesis testing. The benefits and limitation of adaptive design are outlined in [Table 9](#).

Depending upon the adaptations employed, adaptive designs can be classified into several types which are briefly described below.^[23]

Adaptive Randomization Design – This design allows modification of randomization schedules based on varied and/or unequal probabilities of treatment assignment both prospectively and after the review of the response of previously assigned subjects. It assigns more subjects to promising test treatment under investigation and potentially to increase the probability of success of the intended trial. The commonly used adaptive randomization procedures include treatment-adaptive randomization, covariate-adaptive randomization, and response-adaptive randomization. In practice, an adaptive randomization design may be valuable in trials with a relatively small sample size or a trial with short-term outcomes. The issue regarding the balance of patient characteristics between the treatment groups is a concern for this design. The imbalance

Table 9 Possible Benefits and Limitation for Utilizing Adaptive Designs in Clinical Trials

Possible benefits	Limitations
Flexibility for identifying optimal clinical benefits in a more efficient way	Validity and quality/integrity are the major concerns due to possible optional bias caused by adaptations applied
Correct wrong assumption early	Statistical methods for some specific adaptive designs (e.g., less well—understood designs) are not well-established
Select the most promising option early	Criteria for decision-making may not scientifically justifiable
Make use of emerging external information	Statistical inference (e.g., p-value and CI) may not be reliable and the overall type I error rate may not be controlled
React to surprise (positive or negative) early	The role of Data Monitoring Committee (DMC) is not clear
Speed development process	There are some obstacles for implementation

in important characteristics is problematic especially for confirmatory studies.

Adaptive Group Sequential Design – For the classical group sequential design, statistical methods and various stopping boundaries based on different boundary functions for controlling an overall type I error rate are available in the literature.^[23] With adaptations, such as sample size re-estimation based on unblinded interim analyses, the standard methods for the classical group sequential design may not be appropriate, as it may not be able to control the overall type I error rate at the desired level of 5% due to potential issues pertaining to adaptations of a given study design. Appropriate statistical procedures are necessary to avoid the potential increase in the study-wide type I error rate.^[22]

Flexible Sample Size Re-estimation Design – This design allows for sample size adjustment or re-estimation based on the observed data at interim. In general, sample size is determined before the trial formally starts based on pilot estimates of efficacy endpoints and their variability, or a best guess for the lowest clinically meaningful effect size between the treatment and control groups. Practically, parameter misspecification may be inevitable, which can lead to an underpowered design if the true variability is much larger than the initial specification of the variability.^[22] Thus, it is of interest to adjust sample sizes adaptively based on accrued data from the ongoing trial. However, sample size re-estimation suffers from the same disadvantage as the original power analysis for sample size calculation prior to the conduct of the study because it is performed by treating estimates of the study parameters, which are obtained based on data observed at interim, as true values. Sample size adjustment or re-estimation could be done in either a blinded^[24] which is based on overall data or unblinded fashion^[25] which is based on the criteria of treatment effect-size, variability, conditional power, and/or reproducibility probability.

Drop-the-losers Design – This design contains multiple stages which allow (i) dropping the inferior treatment groups, (ii) modifying treatment arms, and/or (iii) adding additional arms after the review of accumulated data at interim. Drop-the-losers design is also known as selection

design or pick-up-the-winner design. A drop-the-losers design is useful in phase II trials with the goal of finding the appropriate dose and frequency of dosing for later phase of clinical development. Typically, drop-the-losers design is the first stage of a two-stage design.^[26] At the end of the first stage, the inferior arms will be dropped based on some pre-specified criteria. The winners will then proceed to the next stage. In practice, the study is often powered for achieving a desired power at the end of the study. In other words, there may not be any statistical power for the analysis at the end of the first stage for dropping the losers. It, however, should be noted the selection criteria and decision rules play important roles for drop-the-losers designs.

Adaptive Dose Finding Design – This design is often used in early phase clinical development to identify the maximum tolerable dose (MTD), which is usually considered as the optimal dose for later phase of clinical development. In practice, it is undesirable to have too many subjects exposed to the dose limiting toxicity (DLT), while it is desirable to have a high probability for achieving the MTD with a limited number of subjects. Thus, the selection of initial dose, dose range, and criteria for dose escalation and/or dose de-escalation is important to the success of the adaptive dose finding design. In recent years, several useful adaptive dose finding designs are proposed in the literature.^[27] Among those methods, continual re-assessment method (CRM) in conjunction with Bayesian approach introduced is usually considered.^[28] For the method of CRM, the dose-response relationship is continually reassessed based on accumulative data collected from the trial. The next patient who enters the trial is then assigned to the potential MTD level. However, a potential disadvantage is that the model may predict a higher MTD due to delayed response and/or a constraint on dose-jump.^[29] It is not uncommon that the sponsors propose CRM-based approaches in their regulatory submissions. In general, CRM-based approaches are considered to be more efficient than that of the commonly used “3+3” rule with respect to accuracy and the allocation of the MTD except when the true dose is among the lower levels.

Biomarker-Adaptive Design – This design allows for adaptations based on the response of biomarkers. This design is useful in the following ways: (i) identify patient population which is most likely to respond to the test treatment under study, (ii) identify natural course of disease, (iii) early detection of disease, and (iv) help in developing personalized medicine.^[30] It should be noted that correlation between biomarker and true clinical endpoint regardless of the treatment given makes a prognostic marker. A prognostic biomarker informs distinct expected clinical outcomes, which is independent of treatment. They provide information about the natural course of the disease in individuals who have or have not received the treatment under study. However, prognostic markers cannot be used to guide to choosing a particular therapy.^[31] In other words, correlation between biomarker and true clinical endpoint does not make a predictive biomarker. A predictive biomarker informs the treatment effect on the clinical endpoint, i.e. it identifies patients who are sensitive or non-sensitive to a given agent. Biomarker-adaptive designs are typically used in exploratory studies which are important in selecting patient population for subsequent trials. This design is imbedded in a confirmatory trial to modify patient eligibility criteria after the interim look. In such a situation, statistical adjustment is needed to avoid increasing the type I error rate.^[32]

Adaptive Treatment-Switching Design – This design allows the investigator to switch a patient's treatment from an initial assignment to an alternative treatment if there is evidence of lack of efficacy, disease progression, or safety of the initial treatment. It is commonly seen in oncology clinical trials due to ethical consideration.^[33] In practice, it is not uncommon that up to 80% of patients may switch from one treatment to another in cancer research. Such a high percentage of subjects who switched due to disease progression could lead to change in hypotheses to be tested and cause further challenges in result interpretation.^[34]

Adaptive-Hypothesis Design – This design allows modifications or changes in hypotheses based on interim analysis results. Modifications of hypotheses of on-going clinical trials based on accrued data can certainly have an impact on the type I error rate, statistical power for testing the hypotheses with the pre-selected sample size for achieving the desired power. The examples include pre-planned switch from a single hypothesis to a composite hypothesis or multiple hypotheses, pre-planned switch the null hypothesis and the alternative hypothesis, and pre-planned change due to switch between the primary study endpoint and the secondary endpoints.

Phase I/II (or Phase II/III) Adaptive Seamless Design – This design combines the study objectives, which are traditionally addressed in separate trials, into one single study. Most commonly used adaptive seamless designs include (i) adaptive seamless phase I/II design, and (ii) adaptive seamless phase II/III design. An adaptive seamless phase I/II design is referred to a design that combines a phase I

trial which usually aims to find MTD for an investigational drug, and a phase II trial which examines the efficacy of the drug at the identified MTD. An adaptive seamless phase II/III design is a two-stage design consisting of a so-called learning or exploratory stage (phase II) and a confirmatory stage (phase III). Thus, an adaptive seamless design may reduce study sample size as compared to traditional designs. In addition, an adaptive seamless design is more efficient because there is no lead time between the two stages. For an adaptive seamless phase II/III design, a typical approach is to power the study for the phase III confirmatory phase and obtain valuable information with certain assurance at the phase II learning stage.

Multiple Adaptive Design – This design includes any combination of the above mentioned adaptive designs. A multiple adaptive design is more flexible but more problematic. Although a multiple adaptive design is more attractive, it makes good statistics practice (GSP) more difficult and challenging in practice.

CONCLUSION

In pharmaceutical development, each design has its own merits and limitations under different circumstances at various stages. How to select an appropriate design for pharmaceutical development when planning a clinical trial is an important question. The answer to this question depends on many factors which include (i) number of treatments to be compared, (ii) characteristics of the treatments, (iii) study objectives, (iv) availability of experimental units (e.g., subjects), (v) inter-subject and intra-subject variability, (vi) duration of the study, and (vii) dropout rates. In conclusion, there is no best design, and the valid statistical designs play an important role to optimize the quality of drug product in pharmaceutical development.

Abstract

This entry provides a definition for pharmacodynamics and describes a number of factors that affect the selection of statistical methods for pharmacodynamics evaluations.

Keywords: Clinical trial; Parametric approach; Pharmacodynamics.

INTRODUCTION

There are several ways of defining pharmacodynamics. Here are three examples.

- i. The branch of pharmacology dealing with the reactions between drugs and living systems.^[1]
- ii. The study of the biochemical and physiological effects of drugs and their mechanisms of action on the body.^[2]
- iii. The study of how drugs can affect the body.^[3]

After being swallowed, injected, inhaled, nasally administered, or absorbed through the skin, most drugs enter the bloodstream, circulate throughout the body, and interact with a number of target sites. Depending on its property or route of administration, a drug may act in only a specific area of the body (e.g., the action of antacids is confined largely to the stomach). When a drug interacts with the target tissues (e.g., cells or organs), a desirable therapeutic effect usually takes place, which is referred to as efficacy or effectiveness in clinical trials. On the other hand, if a drug interacts with cells, tissues, or organs that are not the desired targets, side effects may occur. In clinical trials, side effects are also known as adverse events (AEs) or adverse reactions (ARs). Hence, in a Phase III clinical trial pharmacodynamic (PD) endpoints are primarily safety or efficacy (or both) parameters. Efficacy endpoints are generally more heterogeneous than safety endpoints from one therapeutic area to another because the majority of the safety endpoints are usually restricted to a limited number of specific evaluations, including physical examinations, electrocardiogram (ECG), laboratory variables, vital signs, and adverse-event reporting; drug-level monitoring may also be used to assess safety. For this reason, the focus of the statistical methodologies in this entry is on efficacy parameters and not on safety parameters.

OVERVIEW

The major organ systems in the body include cardiovascular, respiratory, nervous, skin, musculoskeletal, blood, digestive, endocrine, urinary, and reproductive. An investigational drug may be evaluated for efficacy and/or safety for one or more of these systems. In the United States, an investigational new drug (IND) application containing chemistry, toxicity, and other pre-clinical data is submitted to the U.S. Food and Drug Administration (FDA). Other countries utilize a similar process, allowing clinical studies to begin after a review of clinical data. After the investigational drug has been evaluated in clinical trials, a new drug application (NDA) is filed by its sponsoring drug company; this is then reviewed and, hopefully, approved by the Center for Drug Evaluation and Research (CDER) of the FDA. As of 2009, CDER had organized the Office of New Drugs into six divisions: Office of Drug Evaluation I, Office of Drug Evaluation II, Office of Drug Evaluation III, Office of Antimicrobial Products, Office of Nonprescription Products, and Office of Oncology Products. Each division is responsible for evaluating new drugs in some specific therapeutic areas. It is then helpful to understand the therapeutic drug involved and which division of the CDER will be handling the NDA submission; Some meetings are usually held between the division involved and the drug sponsor before IND application and NDA submission in order to reach mutual understanding and agreement about how the investigational drug will be conducted in clinical trials, what type of relevant data will be collected, what endpoints are considered primary and/or secondary, and what statistical consideration is deemed necessary for any study-related issues, and so on.

This entry is organized as follows: The “Introduction” first defines pharmacodynamics. The section “Overview” provides a general overview of some of the primary endpoints for some of the most common diseases within

different organ systems when evaluating pharmacodynamic effects of investigational drugs used in Phase III clinical trials. The section “Factors Affecting the Selection of Statistical Methods for Pharmacodynamic Evaluations” describes a number of factors that affect the selection of statistical methods for pharmacodynamics evaluations. “Other Issues” addresses some additional issues related to Phase II/III pharmacodynamic evaluations.

These pharmacodynamic endpoints discussed in the remainder of this section are often used in clinical trials and agreed upon with regulatory health authorities for the specific indications.

CARDIOVASCULAR SYSTEM

Coronary Artery Disease/Angina

Patient mortality is the most important clinical endpoint in trials assessing the beneficial effects of drugs on coronary artery disease. Such studies often are long term (e.g., five or more years in duration) and may recruit thousands of patients. Patient morbidity (e.g., revascularization, stroke, nonfatal myocardial infarction) are also assessed in such trials. Subjective chest pain and exercise tolerance (stress test) are common endpoints in angina trials.

Hypertension

The mean change from baseline in systolic and diastolic blood pressure and cardiovascular mortality and morbidity are endpoints used in hypertension trials.

Congestive Heart Failure

Patient mortality, exercise tolerance, the number of hospitalizations, and cardiovascular morbidity are common endpoints in trials assessing the effects of drugs in congestive heart failure.

Hyperlipidemia

Low-density lipoprotein, cholesterol levels, and cardiovascular morbidity are endpoints in trials assessing the effect of lipid-lowering agents.

RESPIRATORY SYSTEM

Asthma

Asthma is a very common reaction airway disease. A clinically relevant primary endpoint used in asthma trials is a change in forced expiratory volume in 1 sec (FEV1).

Such FEV1 measurements are determined by spirometry evaluations.

NERVOUS SYSTEM

Alzheimer's Disease

Cognitive and functional scales specifically designed to assess Alzheimer's disease are used as standard endpoints in Alzheimer's trials. Such trials often require that hundreds to thousands of patients be recruited.

Parkinson's Disease

Functional scales specifically designed to assess Parkinson's disease are typically used in evaluating drugs in this disease.

SKIN

Acne

Lesion count and the nature of the lesions (e.g., papular, pustular counts) are commonly used endpoints in acne trials.

Psoriasis

Plaque size, induration, scaling, and redness are generally accepted endpoints in psoriasis trials. Other parameters to be considered include the extent and the severity of psoriatic lesions.

MUSCULOSKELETAL SYSTEM

Osteoarthritis

Tender joints and pain-functional endpoints (e.g., Western Ontario and McMaster Universities Osteoarthritis Index, or WOMAC) are assessed in osteoarthritis trials. The WOMAC is a self-administered questionnaire that is highly reliable and sensitive to changes in health status in patients with osteoarthritis.^[4]

Rheumatoid Arthritis

Endpoints used in trials assessing the safety and efficacy of drugs for rheumatoid arthritis include the number of swollen and painful joints and patient and physician's global assessment of well-being. Radiographic progression of joint destruction is being assessed in current trials with rheumatoid arthritis.

GASTROINTESTINAL SYSTEM

Peptic Ulcer Disease

Endoscopic evidence of improvement or resolution of an ulcer is used as an endpoint in ulcer trials. Symptomatic improvement alone following administration of the investigational drug is *not* sufficient proof of benefit in Phase III ulcer trials.

ENDOCRINE SYSTEM

Diabetes

Diabetes is a systemic disease that may affect multiple organs, including the skin (dermopathy), blood vessels (peripheral vasculopathy), kidney (nephropathy), eyes (retinopathy), and nervous system (neuropathy). Clinical trials in diabetes could assess these clinical endpoints, but they also require laboratory endpoints such as hemoglobin A1C and fasting blood glucose levels.

Osteoporosis

The incidence of bone fracture is a primary efficacy endpoint in osteoporosis trials; because these trials may require a very long duration of follow-up for evaluating bone fractures (e.g., up to five years), bone density has been used as a surrogate marker in osteoporosis trials.

OTHER AREAS

Infectious Diseases

Infections can involve any body system and therefore have many primary endpoints that can be used in clinical trials. The absence of an infectious agent by culture and mortality (e.g., sepsis trials) may be used. In addition, surrogate markers (e.g., viral load in acquired immunodeficiency syndrome [AIDS] studies) have been used.

Oncology

The incidence of patient mortality is an endpoint in many oncology trials. In those instances where there is an extremely high mortality rate, alternative endpoints such as the time of death and tumor burden can be used.

Transplantation

In recent years there has been an increase in the number of drugs approved for use in transplantation as primary or adjunctive immunosuppression for kidney, liver, and heart transplantation. Phase III clinical trials currently use the incidence of acute rejection episodes and patient and graft

survival as necessary endpoints for approval by health authorities.

FACTORS AFFECTING THE SELECTION OF STATISTICAL METHODS FOR PHARMACODYNAMIC EVALUATIONS

The choice of statistical method employed to analyze the pharmacodynamic parameters of interest depends on a number of factors:

- A. Study objective and design.
- B. Type and number of explanatory variables and response variables.
- C. Distribution of the PD parameter.
- D. Model assumptions.
- E. Therapeutic area of the study drug.
- F. Frequency of evaluation of the PD parameter.
- G. Measurements of the PD parameter.
- H. Regulatory concerns of the conduct of a clinical trial.

STUDY OBJECTIVE AND DESIGN

The objectives for Phase III clinical studies may include one or more of the following four objectives:^[5]

- i. Demonstrate/confirm efficacy.
- ii. Establish a safety profile.
- iii. Provide an adequate basis for assessing the benefit-risk relationship to support labeling.
- iv. Establish the dose-response relationship.

A study objective will define what PD parameter is to be considered as the primary clinical endpoint and what comparisons or investigations are deemed most clinically relevant. In Phase III clinical trials, the primary PD parameter is usually an efficacy variable because the primary objective of most Phase III trials is to provide strong scientific evidence on the efficacy of the study drug. The design of the study to evaluate the investigational drug is driven by the study objective. Study design determines how the data from the clinical study are to be collected while minimizing bias and variability from possible extraneous sources in a clinical study. Additionally, a study design that appears to be the most effective one from a statistical perspective may not be suitable or feasible for the study from a clinical or pharmacological perspective.

The most popular study design in Phase III is a parallel group design (known as completely randomized design). Other designs, such as crossover design and factorial design, are also frequently used.

Parallel group design is the simplest design of all. A parallel group design may be extended to include one additional explanatory variable that is used as a blocking

factor. Such a parallel group design with a blocking factor is known as a randomized block design. A parallel group design may include repeated evaluation of the same PD variable over time, which is known as a repeated measurements design.

Usually, there are two or more treatment arms involved in clinical trials, often with one arm assigned to placebo (a placebo-controlled study) or to an active comparator agent (an active-controlled study). Placebo may not be used in any arm because of ethical or other reasons.

Each patient typically receives only one treatment in a parallel group design. In clinical trials where all the treatments are administered to each patient so that he or she can serve as his or her control, a crossover design is the study design of choice. A factorial design is highly desirable when two or more treatments are evaluated simultaneously in the same set of patients through the use of varying combinations of the treatment or when the combinations of two or more explanatory variables (including the treatment) are of interest.

TYPE AND NUMBER OF EXPLANATORY VARIABLES AND RESPONSE VARIABLES

Explanatory variables are also known as independent variables or simply as input variables. Response variables are also called dependent variables or output variables. The response variables throughout this entry are referred to as clinical responses, that is, the PD parameter.

Generally, any data can be classified as either categorical or numerical. A categorical variable is either nominal, when it does not have a natural ordering (e.g., gender), or ordinal, when it is associated with a certain order (e.g., condition of disease, such as mild, moderate, or severe). A numerical variable can be either continuous or discrete. Theoretically, a continuous variable is not countable and can take on any possible value in a certain interval. On the other hand, a discrete variable is countable and in many cases assumes only a finite number of values. A categorical variable, in fact, can be treated as a numerical variable when we can artificially assign numerical values to the categories of a categorical variable. Of course, it is understood that the numerical values of a categorical variable with a nominal scale do not have any meaning in terms of ordering. Based on this argument, we can simply say that a PD variable can be classified as either continuous or discrete (with a nominal scale or an ordinal scale).^[6,7]

In reality, all variables collected from clinical trials should be classified as discrete variables for the following reasons: (i) they are collected from a finite number of patients; and (ii) they are countable. Therefore, the fundamental idea of determining whether a variable is continuous or discrete is dependent upon the number of different values obtained from that variable of interest.

If a variable takes on a small number of values (there is no specific rule as to how small is *small*—it should be relative to the sample size), we can conclude that the variable is discrete. In contrast, if data values encompass a relatively wide range of different values, the variable can be considered continuous.

A commonly used statistical method for evaluating a continuous variable if the data are normally distributed is analysis of variance. In contrast, Fisher's exact test or chi-square test may be applied for categorical-data analysis (i.e., a discrete variable with a nominal or ordinal scale). A continuous variable may be classified as a discrete variable with an ordinal scale. For example, we can categorize a response to antihypertensive therapy in terms of the systolic blood pressure's being either no less than 20% reduction from baseline or less than 20% reduction from baseline.

Additionally, the number of variables (either explanatory or response) or the number of levels for each variable in a clinical trial also affects the selection of certain statistical methods. Here are some examples.

- i. A two-sample *t*-test may be employed if there are only two levels for the only explanatory variable with a continuous scale (i.e., two doses for the treatment), but the same *t*-test cannot be applied if there are three or more treatment levels. In the case in which there are three or more treatment levels, an analysis of variance may be applied.
- ii. Two-way analysis of variance or analysis of covariance may be employed if two explanatory variables are involved.
- iii. A multivariate approach may be considered if there is more than one primary PD parameter to be considered simultaneously.

DISTRIBUTION OF THE PHARMACODYNAMIC PARAMETER

A parametric approach is generally preferred when the PD variable can be justified to be fairly normally distributed. When the continuous PD variable is skewed or not normally distributed, a non-parametric method may be used. In general, a parametric method is more powerful than a non-parametric method. Note that the power of a test is the probability that the null hypothesis is rejected when it is not true.

Sometimes the skewness of the data is attributed to the existence of outliers. The discussion on handling outliers will be detailed under "Regulatory Concerns of the Conduct of a Clinical Trial" because the consideration of removing outlier(s) from a statistical analysis is based not only on statistical concerns but also on regulatory concerns.

As for discrete variables, the most common distributions are binomial, multinomial, and Poisson. Logit (log of odds)

models are used with binomial and multinomial distributions. The log-linear model is used with the Poisson distribution.

MODEL ASSUMPTIONS

A parametric approach is used in a conventional statistical model along with a number of assumptions. The assumption of normality is only the first step to determine the suitability of a parametric method. There are other conditions required for a specific model, including the following:

- i. *Independence*: Most of the models require independence of the data. This means that the observations from different treatments are obtained from different patients. A different model needs to be considered when observations are dependent, such as the data from a study with a crossover design or from a study with repeated measures.
- ii. *Homogeneous variance*: Equal variability is required in the approach with conventional analysis of variance. When this requirement is not met, there are two possible solutions: (i) use an algebraic transformation such as log to reduce the observations in a much smaller scale, in hopes of achieving the equality of variance; (ii) employ a more advanced method, such as a generalized *F*-test^[8] that does not require equal variance in the model. However, the software program to accommodate such methodologies for exact tests does not exist in SAS.

THERAPEUTIC AREA OF THE STUDY DRUG

In almost all cases, time should be considered a continuous variable. Intuitively, we may think about applying analysis of variance to analyze “time” when it is the primary PD parameter, but this is not always the case. For example, in a clinical trial to assess an analgesic drug, the onset time (the time that the degree of pain starts to diminish) can be a primary PD parameter. Analysis of variance can be applied to compare the mean onset time among different treatment groups. However, in cancer trials, survival analysis may be more appropriate (e.g., in a patient with cancer, the time to survival after a treatment). In summary, the mean time can be generally compared with a *t*-test or analysis of variance, but the time to the first predefined event is usually analyzed with a survival analysis.

FREQUENCY OF EVALUATION OF THE PHARMACODYNAMIC PARAMETER

When a PD parameter is evaluated more than once throughout a clinical trial, it is more appropriate to employ

a method that takes into account the repeated measures. A method such as one-way analysis of variance with repeated measures may be appropriate for such a trial.

MEASUREMENTS OF PHARMACODYNAMIC PARAMETERS

The measurement of a primary PD parameter in a clinical trial protocol must be clearly defined. For example, it is not adequate to indicate that mortality is the primary parameter in a cancer trial. Mortality can be assessed in many ways: the proportion of patients alive at a pre-determined point in time, the overall survival curve, the mean survival time during a fixed time interval, or a combination of assessments.

When a continuous PD variable has been determined, the change from baseline or the percentage change from baseline may be of most interest. One major concern with such a measure is the direction of the change, which may be above or below baseline, so the average of such a measure from all patients could be misleading; for example, the elevation or decrease of blood glucose from baseline is an important indication for a diabetes trial assessing a hypoglycemic agent. On the other hand, if only the magnitude of the change (or percentage change) is considered, the probability distribution of this absolute value of this derived PD variable may not be easily identified and would greatly impact the conduct of the hypothesis testing for the trial.

As discussed earlier, a continuous variable can be converted into a discrete variable with an ordinal scale. When such a conversion is deemed clinically relevant, the employment of statistical methods should be adjusted accordingly.

REGULATORY CONCERNS ABOUT THE CONDUCT OF A CLINICAL TRIAL

In January 1997, the FDA published a draft guideline on statistical principles for clinical trials.^[9] It addresses statistical considerations about handling a number of potential issues for a clinical trial. They include the following.

Type of Comparison

This is closely related to the study objective and will determine how the hypothesis testing should be set up: a two-sided test, a one-sided test (a right-tailed test or a left-tailed test). The following three possible comparisons are usually demonstrated in Phase III trials.

Superiority Trials

These are meant to demonstrate that the study drug is superior to placebo in a placebo-controlled study or is superior

to an active control treatment. Generally, superiority trials are assumed, unless it is explicitly stated otherwise.

Equivalence Trials

Some examples:

- i. Pharmacokinetic bioequivalence trials to show two formulations are bioequivalent or a generic drug is bioequivalent to an innovator drug
- ii. Show equivalence between a comparator agent at one dose level and the study drug at a lower dose level
- iii. Show equivalence between two different dosing regimens of the study drug with an identical total dose, such as 150 mg twice a day (b.i.d.) vs. 100 mg three times a day (t.i.d.).

Non-inferiority Trials

These can be seen in many active-controlled studies to show that the efficacy of an investigational drug is no worse than that of the comparator drug. In some situations, a trial can be designed to add a placebo arm to an active-controlled study so that the objectives of the study are to establish superiority to the placebo and to show a similar efficacy (and/or safety) profile to the comparator agent.

Patient Population Included in the Statistical Analysis

This does not affect the decision-making in terms of statistical approaches, but it would certainly influence the results and interpretation of the results. The following two types of patient populations are generally allowed in the statistical analysis.

All Randomized Patients

An analysis based on this population is also well known as an “intent-to-treat” analysis. In theory, the analysis should include all eligible patients who were randomized to the study treatments. In practice, it often excludes patients who did not receive any dose of study treatments (including placebo) or did not have any data post-randomization. Two major problems arise in this case: First, should we include patients who may fall into one of the following problems: protocol violation, error in treatment assignment, or use of prohibited medications during the study? Second, in which treatment group should a patient be placed in the statistical analysis if he is not treated with the assigned study drug? For example, should the patient be in treatment group A or B if he actually received treatment B but was randomized to treatment A? There is no clear direction in the guidelines as to how to resolve these problems; they should be handled case by case.

Per-Protocol Patients

An analysis using this patient population is referred to as evaluable patients analysis. Evaluable patients should be defined as concisely as possible in the protocol or at latest before the unblinding of the treatment. Any change to the definition after unblinding has to be justified.

Handling Missing Values and Outliers

Missing values do occur in almost every clinical trial. Unfortunately, there is no universally applicable method for handling missing values. The best way is to predefine the methods to be used for missing values in the analysis plan, especially for the study that may involve a substantial number of missing values. As with the handling of missing values, the statistical method for detecting outliers should be well described before the treatment codes are unblinded. The removal of outliers from statistical analysis will be more convincing when the outliers can be justified clinically as well as statistically.

SUMMARY

A selection of a specific statistical method for evaluating PD parameters in a clinical trial should be carefully based on all of the factors just discussed. This will help a sponsoring pharmaceutical company to get the study drug approved by the FDA by employing an appropriate statistical method (it may be a very simple one) that is acceptable from statistical, medical, and regulatory standpoints.

OTHER ISSUES

There are a number of additional issues that have received specific attention by the FDA for evaluations of new drugs. Since there is no absolute statistical method to handle these specific topics, these will be discussed from clinical and regulatory perspectives.

Surrogate Markers

Surrogate markers are now being considered as appropriate target endpoints for various diseases in clinical trials, especially in those diseases where the surrogate marker has been validated (e.g., acute rejection episodes as a predictor of chronic organ rejection), where medical need may justify a rapid assessment (e.g., T-cell count because of the high mortality from AIDS), or where the duration of a trial (bone fracture endpoint in osteoporosis trials) or the number of patients required for enrollment (e.g., rare medical conditions) may be problematic.

A surrogate endpoint is an endpoint that is intended to relate to a clinically important outcome but does not in

itself measure a clinical benefit. Surrogate endpoints may be used as primary endpoints when appropriate (when the surrogate is reasonably likely or well known to predict a clinical outcome^[10]). The clinical conclusions may be misleading if the selected surrogate endpoints for the studies are not vigorously established. Fleming^[11] discusses details of using surrogate markers in clinical trials, and Fleming and DeMets^[12] present examples of surrogate endpoints that failed to be validated in clinical trials.

Subgroup Considerations

Particular subgroups deserve special PD consideration because of unique characteristics, thereby requiring the need to evaluate such subgroups separately in clinical trials. These subgroups include the elderly and pediatric populations, different races, gender differences, and medical conditions that could affect PD interpretation. It would therefore be appropriate in these subgroups to analyze the PD effects of a drug separate from the rest of the trial population.

Elderly Population

It is well known that the elderly population is different from the younger population with respect to sensitivity to many drugs.^[13] For example, patients treated with nonsteroidal anti-inflammatory agents have a higher incidence of gastrointestinal bleeding than do younger patients. The FDA also provides guidance on the need for collecting information on geriatric patients.^[14] There is no clear definition of a geriatric population; normally this includes patients 65 years old and older. However, the FDA encourages drug companies to include patients in clinical studies, if possible, who are 75 years old and older.

Pediatric Population

Body surface area is different in very young children, compared to adolescents or adults; this often requires dosing of a drug on a milligram per kilogram basis compared to adults, among whom body surface area is not dramatically different. Bowel length is much shorter in very young children, which is well known to affect the pharmacokinetics of a drug and therefore the PD endpoints in a clinical trial.

When pediatric patients are to be considered for participation in clinical trials, safety data from adult patients should be available.^[15] In addition, for a drug expected to be used in children, evaluation should be made in the appropriate group. When a drug is to be evaluated in children, it is usually appropriate to begin with older children before extending the trial first to younger children and then to infants.^[5]

Racial Differences

When a new drug is to be developed globally, the drug may be tested among different ethnic groups. It is highly

suggested by the FDA that such a drug be characterized as ethnically sensitive or insensitive. A new chemical entity (NCE) is said to be sensitive to ethnic factors when its pharmacokinetic, PD, or other characteristics suggest the potential for clinically significant impact by intrinsic and/or extrinsic ethnic factors on safety, efficacy, or dose response. Extrinsic ethnic factors are factors associated with the patient's environment and/or culture. Extrinsic factors tend to be less genetically and more culturally and behaviorally determined. Examples are medical practice, diet, socioeconomic status, and exposure to pollution and sunshine. Intrinsic ethnic factors are characteristics associated with the drug recipient. These are factors that help to define and identify a subpopulation and that may influence the ability to extrapolate clinical data between ethnic groups (or between regions). Examples of intrinsic ethnic factors include polymorphism, age, gender, height, weight, lean body mass, body composition, and organ dysfunction.^[16]

The following is an example of a drug showing its sensitivity to ethnic factors: African Americans have been reported to have less drug bioavailability from immunosuppressive drugs administered after transplantation, which has been attributed to lower absorption compared to the Caucasian population. This pharmacokinetic difference has a significant impact on the PD endpoint of acute rejection because African Americans who receive kidney transplants are known to have poorer graft survival.^[17]

Gender Differences

Because of unique anatomy and physiology, women are known to have complex pharmacokinetics different from men.^[18] Although pharmacokinetic differences between men and women have been extensively reported, less is known about PD differences between men and women.

Issues related to pregnancy and oral contraceptive use appear to be important.^[19] Pregnancy may increase the metabolism of anti-epileptic drugs, and oral contraceptives are well known to interfere with the metabolism of many drugs; on the other hand, certain drugs may impair contraceptive efficacy. Women have been reported to be more prone to develop torsade de pointes from drugs such as quinidine and procainamide than men, and women have been reported to have less sensitivity to insulin than men. Ongoing research in this area will delineate additional PD differences between men and women.

Patients with Impaired Renal or Liver Function

After entering the body, a drug is eliminated either by excretion or by metabolism. Whereas elimination can occur via any of several routes, most drugs are cleared either by elimination of unchanged drug by the kidney or by metabolism in the liver. For a drug eliminated primarily via renal excretory mechanisms, impaired renal function may alter its PK and PD to an extent that the

dosage regimen needs to be changed from that used in patients with normal renal function. Whereas the most obvious type of change arising from renal impairment is a decrease in renal excretion (or possibly renal metabolism) of a drug or its metabolites, renal impairment has also been associated with other changes, such as changes in hepatic metabolism, plasma protein binding, and drug distribution. These changes may be particularly prominent in patients with severely impaired renal function and have been observed even when the renal route is not the primary route of elimination of a drug.^[20]

Meta-Analysis

The results from more than one clinical trial may be combined in order to draw a more robust clinical conclusion. A meta-analysis of clinical trials may also be necessary when data exist from multiple studies that are each insufficiently powered to reach statistically significant conclusions or if each study has a limited number of enrolled patients (because of logistical or other reasons). There is a substantial amount of literature published in this area [e.g., Hedges and Olkin,^[21] Hunter and Schmidt,^[22] and Geller and Proschan^[23]].

Pharmacokinetic/Pharmacodynamic Relationships

During recent drug development and evaluation efforts, PK/PD relationships have been a focus because the combination of these two areas, through an appropriate modeling, will lead to the therapeutically most relevant relationship between pharmacological effect and time and will produce an optimal dose recommendation. Pharmacokinetic data and PD data can be linked directly or indirectly. The direct or indirect link will play an important role in determining an appropriate mathematical PK/PD model.^[24]

CONCLUSION

As drug development advances at an unprecedented pace with much more complicated technology, the challenge of encountering more and more—not-easy-to-be-resolved medical and statistical issues—is inevitable. This certainly will make the pharmaceutical industry one of the most attractive and challenging opportunities for statisticians.

Abstract

This entry discusses several univariate statistical methods that are used mostly for Phase III clinical studies for considering explanatory factors other than treatment variable and pharmacodynamic (PD) response.

Keywords: ANOVA; Covariate; Linear regression; Logistic regression.

INTRODUCTION

In this entry, we will discuss several univariate statistical methods that are used mostly for Phase III clinical studies for considering explanatory factors other than treatment variable and pharmacodynamic (PD) response. We specify the underlying conditions (including study design, model assumptions, and number of data points per patient) that apply to each method. Note that the “explanatory variable” refers to treatment (or dosage level) and any other variable used as the stratified variable or covariate. In this entry, we will classify the explanatory variable as a “treatment” variable or as an “other explanatory” variable. “Response variable” refers to the PD parameter, and we will consider only the clinical trials with a single primary PD parameter.

We will divide clinical trials into five groups according to the type of PD parameter and the number and type of explanatory variables. Table 1 displays the summary of these five groups.

The discussion of each statistical method will cover purpose, statistical model, hypothesis testing, test statistic, rejection region, confidence interval, two-sided p -value, description of and notes on the method, and any related SAS procedure. (SAS, the most popular statistical software package, is also accepted by the Food and Drug Administration as one of the standard packages.

The statistical methods discussed for each group are listed in Table 2.

STATISTICAL METHODS

Group 1

Two-Way Analysis of Variance

Study Design: Parallel group design with a blocking factor.

Model Assumptions: Normal distribution, independence, equal variance for all treatments.

Number of Observations per Patient for PD Parameter: 1.

Purpose:

- To compare the equality of treatment means.
- To compare the equal block effect.
- To determine the interaction effect.

Statistical Model: $y_{ijm} = \mu + \tau_i + \eta_j + \tau\eta_{ij} + \varepsilon_{ijm}$, for $i = 1, 2, \dots, k$; $j = 1, 2, \dots, s$; $m = 1, 2, \dots, n_{ij}$ where

- Y_{ijm} = PD value for patient m in treatment group i and block j
- μ = unknown overall population mean
- τ_i = unknown treatment effect for treatment group i
- η_j = unknown j th block effect
- $\tau\eta_{ij}$ = interaction effect of i th treatment with j th block
- ε_{ijm} = random error associated with patient m in treatment group i and block j

Analysis of Variance Summary: See Table 3.

Table 1 Classification for Model Grouping

	PD variable		Explanatory variables			
	Continuous (C) vs. discrete (D)	No. of values ^a	Treatment variable	Other explanatory variables	Continuous (C) vs. discrete (D)	No. of values
1	C	—	2 or more	1	D	2 or more
2	C	—	2 or more	1	C	—
3	D	2	2	1	D	2 or more
4	D	2	2 or more	1 or more	C or D	2 or more
5	C	—	2 or more	1 or more	C or D	2 or more

^aWhen “C” is specified, this column is not needed.

Table 2 Statistical Methods for Each Group

Group	Statistical methods
1	Two-way analysis of variance Crossover design One-way analysis of variance with repeated measures
2	Linear regression One-way analysis of covariance
3	Cochran-Mantel-Haenszel test
4	Logistic regression
5	Cox proportional hazards analysis

Computation for Sum of Squares:

$$\begin{aligned}
 SS(T) &= \sum_{i=1}^k \sum_{j=1}^s \sum_{k=1}^{n_{ij}} (\bar{y}_{i..} - \bar{y}_{...})^2 \\
 SS(B) &= \sum_{i=1}^k \sum_{j=1}^s \sum_{k=1}^{n_{ij}} (\bar{y}_{.j.} - \bar{y}_{...})^2 \\
 SS(TB) &= \sum_{i=1}^k \sum_{j=1}^s \sum_{k=1}^{n_{ij}} (\bar{y}_{ij.} - \bar{y}_{i..} - \bar{y}_{.j.} + \bar{y}_{...})^2 \\
 SS(E) &= \sum_{i=1}^k \sum_{j=1}^s \sum_{k=1}^{n_{ij}} (y_{ijk} - \bar{y}_{ij.})^2 \\
 SS(TOT) &= \sum_{i=1}^k \sum_{j=1}^s \sum_{k=1}^{n_{ij}} (y_{ijk} - \bar{y}_{...})^2 \\
 \bar{y}_{i..} &= \sum_{j=1}^s \sum_{k=1}^{n_{ij}} y_{ijk} / n_{i.}, \quad n_{i.} = \sum_{j=1}^s n_{ij} \\
 \bar{y}_{.j.} &= \sum_{i=1}^k \sum_{k=1}^{n_{ij}} y_{ijk} / n_{.j}, \quad n_{.j} = \sum_{i=1}^k n_{ij} \\
 \bar{y}_{ij.} &= \sum_{k=1}^{n_{ij}} y_{ijk} / n_{ij} \\
 \bar{y}_{...} &= \sum_{i=1}^k \sum_{j=1}^s \sum_{k=1}^{n_{ij}} y_{ijk} / n, \quad n = \sum_{i=1}^k \sum_{j=1}^s n_{ij}
 \end{aligned}$$

Table 3 Analysis of Variance Summary for Parallel Group Design with a Blocking Factor

Source of variation	Degrees of freedom	Sum of squares	Mean squares
Treatment	$k - 1$	SS(T)	MS(T)
Block	$s - 1$	SS(B)	MS(B)
Treatment $\times$ block	$(k - 1)(s - 1)$	SS(TB)	MS(TB)
Error	$N - sk$	SS(E)	MS(E)
Corrected total	$N - 1$	SS(TOT)	—

Hypothesis Testing for Treatment Effect:

- $H_0: \tau_i = 0$ for all i vs. $H_a: \tau_i \neq 0$ for some i if treatment effect fixed.
- $H_0: \sigma_\tau^2 = 0$ vs. $H_a: \sigma_\tau^2 \neq 0$ if treatment effect random.

Test Statistic for Treatment Effect:

$$F_0 = \frac{MS(T)}{MS(E)} \quad \text{for fixed-treatment effect}$$

$$F_0 = \frac{MS(T)}{MS(TB)} \quad \text{for random-treatment effect}$$

Rejection Region at α Level:

- $F_0 > F_{(s-1, N-k), 1-\alpha}$ for fixed-treatment effect.
- $F_0 > F_{(s-1, (k-1)(s-1)), 1-\alpha}$ for mixed- or random-treatment effect.

Two-Sided p Value:

- $1 - \text{PROBF}(F_0, k - 1, N - sk)$ for fixed-treatment effect.
- $1 - \text{PROBF}(F_0, k - 1, (k - 1)(s - 1))$ for random-treatment effect.

Hypothesis Testing for Block Effect:

- $H_0: \eta_i = 0$ for all i vs. $H_a: \eta_i \neq 0$ for some i if treatment effect fixed.

- b. $H_0: \sigma_\eta^2 = 0$ vs. $H_a: \sigma_\eta^2 \neq 0$ if treatment effect random.

Test Statistic for Block Effect:

$$F_0 = \frac{MS(B)}{MS(E)} \quad \text{for fixed-block effect}$$

$$F_0 = \frac{MS(B)}{MS(TB)} \quad \text{for random-block effect}$$

Rejection Region at α Level:

- $F_0 > F_{(s-1, N-k), 1-\alpha}$ for fixed-block effect.
- $F_0 > F_{(s-1, (k-1)(s-1)), 1-\alpha}$ for random-block effect.

Two-Sided p Value:

- $1 - \text{PROBF}(F_0, s-1, N-sk)$ for fixed-block effect.
- $1 - \text{PROBF}(F_0, s-1, (k-1)(s-1))$ for random-block effect

Hypothesis Testing for Treatment-by-Block Interaction Effect:

- a. $H_0: \tau\eta_{ij} = 0$ for all i, j vs. $H_a: \tau\eta_{ij} \neq 0$ for some i, j for fixed model.
- b. $H_0: \sigma_{\tau\eta}^2 = 0$ vs. $H_a: \sigma_{\tau\eta}^2 \neq 0$ for mixed or random model.

Test Statistic for Interaction Effect: $F_0 = MS(TB)/MS(E)$ for any model.

Rejection Region: $F_0 > F_{((k-1)(s-1), N-sk), 1-\alpha}$.

Two-Sided p Value: $1 - \text{PROBF}(F_0, (k-1)(s-1), N-sk)$.

Related SAS Procedure: PROC GLM (or MIXED or ANOVA).

Description of and Notes on the Method:

- a. This model requires one other explanatory variable (a discrete variable) that serves as the blocking factor in the model.
- b. The model may apply to the situation in which two drugs are the treatment and blocking factors, and the combination of the two drugs is the interaction effect. In this case, the treatment randomization schedule is very likely to be generated with a full consideration of each factor and the combination, and the sample size for the study is estimated appropriately to show a sufficiently high power (≥ 0.80). For those situations where the blocking factor is a stratified variable, such as gender, race, age group, or underlying disease condition, the treatment randomization schedule in many cases does not take into account the stratification, so the near-equal number of sample size for each stratified variable may not occur. In addition, the sample size calculation, again in most cases, is based on the treatment difference only. Hence, the result from

the study may not provide strong power for the statistical significance for the blocking effect as well as for the interaction effect.

- c. The treatment randomization schedule is normally based on the number of k groups if the blocking factor is a stratified factor, and it will be based on the number of ks groups for a drug combination study.
- d. If the blocking factor represents the center effect for a multi-center study, the sample size for each center may vary to a great degree. In some cases, several small centers may be collapsed into a single “dummy” center in order to reduce the degrees of freedom for center effect and to increase the sample size for each center. In reality, the treatment effect will be difficult to conclude in a trial where the treatment by center interaction is statistically significant for a trial with a large number of centers and the treatment effect goes in different directions among centers (e.g., in a trial with 50 centers and two treatment groups, 50% of the 50 centers showed that treatment A is superior to treatment B, and the remaining 50% centers showed that treatment A is inferior to treatment B).
- e. The model is “fixed” if both treatment and block effects are fixed; the model is “random” when both treatment and block effects are random. It is a “mixed” model when one of the two effects (treatment or block) is random and the other is fixed.
- f. The model is “balanced” when all the cells have the same number of observations; otherwise, it is “unbalanced.”
- g. There are four ways of computing sum of squares in SAS for unbalanced data, known as Type I through Type IV. In general, Type III sum of squares is selected.^[1,2]
- h. The interaction term can be ignored if every cell contains only one observation or the interaction effect is insignificant. In this case, the model is reduced to a model with a randomized block design.
- i. If the treatment effect represents different dose levels (including the placebo) of a study drug, it is desirable to investigate the trend effect, such as linear or quadratic. This can also apply to the blocking factor if it is measured on an ordinal scale. In such a case, the interaction term can be decomposed into the combination of those trends, such as $T_{\text{linear}} \times B_{\text{linear}}$ or $T_{\text{linear}} \times B_{\text{quadratic}}$.
- j. PROC ANOVA in SAS can be applied to a balanced case only. PROC GLM is developed mainly for the use of the fixed-effect model. PROC MIXED is a new SAS procedure designed to handle the more complicated, so-called mixed model.
- k. Confidence intervals for each level of treatment factor (and/or blocking factor) as well as for the mean

difference between two levels for the same factor can be constructed via a T distribution, but note that the standard error used in the confidence interval depends on the type of factor (fixed or random).

- l. Multiple comparisons may be desirable to determine pairwise differences between various levels of the treatment effect if the treatment effect is deemed significant.
- m. There are a number of other methodologies proposed for combination drug trials, such as response surface method.^[3-5]
- n. This two-way analysis of variance can be extended to any higher order (≥ 3) of analysis of variance (i.e., a study with two or more “other explanatory variables”). With a higher-order analysis of variance, many different types of interaction exist.

Crossover Design (Using A 2×2 Crossover Design for Illustration)

Study Design: Crossover design.

Model Assumptions: Normal distribution, dependence, equal variance for all treatments, compound symmetry.

Number of Observations per Patient for PD Parameter: 2.

Purpose: To compare the equality of treatment means.

Statistical Model: $y_{ijm} = \mu + Q_i + S(Q)_{m(i)} + P_j + \tau_{(ij)} + \varepsilon_{ijm}$, for $i, j = 1, 2; m = 1, 2, \dots, n_i$ where

- y_{ijm} = PD value for patient m in period j in treatment sequence i
- μ = overall population mean
- Q_i = effect of i th sequence
- $S(Q)_{m(i)}$ = error term associated with m th subject in sequence i
- $\tau_{(i,j)}$ = treatment effect in period j for treatment sequence i
- P_j = effect for j th period
- ε_{ijm} = random error associated with patient m in treatment sequence i and period j

Analysis of Variance Summary: See [Table 4](#).

Computation for Sum of Squares:

Table 4 Analysis of Variance Summary for 2×2 Crossover Design

Source of variation	Degrees of freedom	Mean squares
Sequence	1	MS(Q)
Subject (sequence)	$n_1 + n_2 - 2$	MS(S(Q))
Treatment	1	MS(T)
Period	1	MS(P)
Error	$n_1 + n_2 - 2$	MS(E)
Corrected total	$2(n_1 + n_2) - 1$	MS(TOT)

$$MS(Q) = \sum_{i=1}^2 \sum_{j=1}^2 \sum_{m=1}^{n_i} (\bar{y}_{i..} - \bar{y}_{i...})^2$$

$$MS(S(Q)) = \frac{\sum_{i=1}^2 \sum_{j=1}^2 \sum_{m=1}^{n_i} (\bar{y}_{i.m} - \bar{y}_{i..})^2}{n_1 + n_2 - 2}$$

$$MS(T) = \sum_{i=1}^2 \sum_{j=1}^2 \sum_{m=1}^{n_i} (\bar{y}_{ij.} - \bar{y}_{i..})^2$$

$$MS(P) = \sum_{i=1}^2 \sum_{j=1}^2 \sum_{m=1}^{n_i} (\bar{y}_{.j.} - \bar{y}_{i...})^2$$

$$SS(TOT) = \sum_{i=1}^2 \sum_{j=1}^2 \sum_{m=1}^{n_i} (\bar{y}_{ijk} - \bar{y}_{i...})^2$$

Hypothesis Testing for Treatment Effect: $H_0: \tau_1 = \tau_2$ vs.

$$H_a: \tau_1 \neq \tau_2$$

Test Statistic for Treatment Effect: $F_0 = MS(T)/MS(E)$.

Rejection Region at α Level: $F_0 > F_{(1, n_1 + n_2 - 2, 1 - \alpha)}$.

Two-Sided p Value: $1 - \text{PROBF}(F_0, 1, n_1 + n_2 - 2, 1 - \alpha)$.

Hypothesis Testing for Period Effect: $H_0: P_1 = P_2$ vs.

$$H_a: P_1 \neq P_2$$

Test Statistic: $F_0 = MS(P)/MS(E)$.

Rejection Region at α Level: $F_0 > F_{(1, n_1 + n_2 - 2, 1 - \alpha)}$.

Two-Sided p Value: $1 - \text{PROBF}(F_0, 1, n_1 + n_2 - 2)$.

Related SAS Procedure: PROC GLM (or MIXED).

Description of and Notes on the Method:

- a. We use a 2×2 crossover design as an example for illustration.
- b. One discrete “other explanatory variable” is required. The “period” factor is the “other explanatory variable” in this model.
- c. This is used to compare two treatments with the removal of the time effect because each treatment is administered in both dosing periods to all patients. Each patient serves as his or her control.
- d. There are two major sources of variation: inter-subject variation and intra-subject variation. In this model, the inter-subject variation is composed of two components: sequence and patient within sequence; the intra-subject variation contains three components: treatment, period, and error.
- e. There are two types of variability associated with crossover design: between-patient variability and within-patient variability. MS(S(Q)) in the analysis of variance refers to the between-patient variance, and (MS(E)) refers to the within-patient variance.
- f. This model is commonly used in a Phase I PK bio-equivalence study.
- g. It is important that the study allow a sufficiently long wash-out period between the two treatment administrations to avoid the carryover effect.
- h. This model assumes no carryover effect.

- It is important that a baseline value be obtained in each period.
- The model can be extended to a higher-order number of treatments and time periods. Note that using a higher-order crossover study may potentially increase the dropout rate because the duration of study is prolonged, and when an odd number of treatments is used for a clinical study, it would be necessary to employ William's design in order to maintain the equal number of appearances for each ordered pair of treatments.
- The crossover design is not suitable for study drugs with long terminal half-lives or for study drugs with irreversible PD responses.
- In theory, repeated measures is defined as a series of the same information (data) taken under the same experimental condition from the same patient over time. Therefore, strictly speaking, this crossover design should not be classified as a case of a repeated-measures design.
- "Compound symmetry" means that the correlations between each pair of two time points are the same. Mauchly's criterion can be used for this purpose, which is also available in SAS GLM REPEATED PROCEDURE.^[6]
- When there are repeated measures for each period, the analysis proposed by Wallenstein and Fisher can be used.^[7]
- This analysis assumes a fixed-effect model.
- A confidence interval for treatment mean difference can be obtained.
- In general, patients with missing values are removed from the statistical analysis.

One-Way Analysis of Variance with Repeated Measures

Study Design: Parallel group design with a time factor.

Model Assumptions: Normal distribution, independence, equal variance, compound symmetry.

Number of Observations per Patient for PD Parameter: Multiple.

Purpose:

- To determine each treatment profile over a period of time.
- To compare the treatment effects.

Statistical Model: $y_{ijm} = \mu + \tau_i + S_{j(i)} + T_m + \tau T_{im} + \varepsilon_{ijm}$ for $i = 1, 2, \dots, k; j = 1, 2, \dots, n_i; m = 1, 2, \dots, p$ where

- y_{ijm} = PD value for patient j at time m in treatment group i
- μ = overall population mean
- τ_i = treatment effect for treatment group i
- $S_{j(i)}$ = effect for j th patient in treatment group i
- T_m = effect at m th time point

- τT_{im} = interaction effect of i th treatment with m th time point
- ε_{ijm} = random error associated with patient j in treatment group i at time j

Analysis of Variance Summary: See Table 5.

Computation for Sum of Squares:

$$\begin{aligned} SS(T) &= \sum_{i=1}^k \sum_{j=1}^{n_i} \sum_{m=1}^p (\bar{y}_{i..} - \bar{y}_{...})^2 \\ SS(BET) &= \sum_{i=1}^k \sum_{j=1}^{n_i} \sum_{m=1}^p (\bar{y}_{ij.} - \bar{y}_{i..})^2 \\ SS(TIME) &= \sum_{i=1}^k \sum_{j=1}^{n_i} \sum_{m=1}^p (\bar{y}_{.m} - \bar{y}_{...})^2 \\ SS(T \times TIME) &= \sum_{i=1}^k \sum_{j=1}^{n_i} \sum_{m=1}^p (\bar{y}_{i.m} - \bar{y}_{i..} - \bar{y}_{.m} + \bar{y}_{...})^2 \\ SS(TOT) &= \sum_{i=1}^k \sum_{j=1}^{n_i} \sum_{m=1}^p (\bar{y}_{ijm} - \bar{y}_{...})^2 \\ SS(W) &= SS(TOT) - SS(T) - SS(BET) \\ &\quad - SS(TIME) - SS(T \times TIME) \end{aligned}$$

where

$$\begin{aligned} \bar{y}_{i..} &= \sum_{j=1}^{n_i} \sum_{m=1}^p y_{ijm} / pn_i \\ \bar{y}_{.m} &= \sum_{i=1}^k \sum_{j=1}^{n_i} y_{ijm} / N \\ \bar{y}_{ij.} &= \sum_{m=1}^p y_{ijm} / p \\ \bar{y}_{i.m} &= \sum_{j=1}^{n_i} y_{ijm} / n_i \\ \bar{y}_{...} &= \sum_{i=1}^k \sum_{j=1}^{n_i} \sum_{m=1}^p y_{ijm} / pN \text{ and } N = \sum_{i=1}^k n_i \end{aligned}$$

Table 5 Analysis of Variance Summary for Parallel Group Design with a Time Factor

Source of variation	Degrees of freedom	Sum of squares	Mean squares
Treatment	$k - 1$	SS(T)	MS(T)
Patient (treatment)	$N - k$	SS(BET)	MS(BET)
Time	$p - 1$	SS(TIME)	MS(TIME)
Treatment $\times$ Time	$(k - 1)(p - 1)$	SS(T $\times$ Time)	MS(T $\times$ Time)
Error	$(N - k)(p - 1)$	SS(W)	MS(W)
Corrected total	$Np - 1$	SS(TOT)	

Hypothesis Testing for Treatment Effect: $H_0: \tau_i = 0$ for all i vs. $H_0: \tau_i \neq 0$ for some i

Test Statistic for Treatment Effect: $F_0 = \text{MS}(T)/\text{MS}(\text{BET})$.

Rejection Region for Treatment Effect: $F_0 > F_{(k-1, N-k), 1-\alpha}$.

Two-Sided p Value for Treatment Effect: $1 - \text{PROBF}(F_0, k-1, N-k)$.

Hypothesis Testing for Time Effect: $H_0: T_m = 0$ for all m vs. $H_0: T_m \neq 0$ for some m

Test Statistic for Time Effect: $F_0 = \text{MS}(\text{TIME})/\text{MS}(W)$.

Rejection Region for Time Effect: $F_0 > F_{(p-1, (N-k)(p-1)), 1-\alpha}$.

Two-Sided p Value for Time Effect: $1 - \text{PROBF}(F_0, p-1, (N-k)(p-1))$.

Hypothesis Testing for Treatment-by-Time Interaction Effect:

$H_0: \tau T_{im} = 0$ for all i, m vs. $H_0: \tau T_{im} \neq 0$ for some i, m

Test Statistic for Interaction Effect: $F_0 = \text{MS}(T \times \text{TIME})/\text{MS}(W)$.

Rejection Region for Interaction Effect: $F_0 > F_{((k-1)(p-1), (N-k)(p-1)), 1-\alpha}$.

Related SAS Procedure: PROC GLM or PROC MIXED.

Description of and Notes on the Method:

- One discrete “other explanatory variable” is required. The “time” factor is the “other explanatory variable” in this model.
- Repeated measures can be collected in at least two ways:
 - They are over a certain period of time within the same visit (e.g., measurement of blood pressure over 24 hours post-treatment at one clinic visit). In this case, there is only one baseline.
 - They are collected at a number of visits, with one observation per visit. In this case, a baseline at each visit is highly desirable.
- Compound symmetry has to be examined to ensure the validity of the model.
- The preceding discussion points apply to the fixed model only; in other words, both treatment and time effects are fixed. This is generally what the model assumes for Phase III clinical trials because the dosage levels and time points are selected with clinical reasons.
- When a mixed or a random model is encountered, then the test statistic employed to test the time effect is $F_0 = \frac{\text{MS}(\text{TIME})}{\text{MS}(T \times \text{TIME})}$. As for the test of the treatment effect, a pseudo- F -test of the form $\frac{\text{MS}(T)}{\text{MS}(\text{BET}) + \text{MS}(T + \text{TIME}) - \text{MS}(W)}$ can be obtained, which approximates an F distribution with $(k-1, w)$ degrees of freedom, where (Ref. [6], pp. 509–512; Ref. [8])

$$w = \frac{[\text{MS}(\text{BET}) + \text{MS}(T \times \text{TIME}) - \text{MS}(W)]^2}{\frac{(\text{MS}(\text{BET}))^2}{N-k} + \frac{(\text{MS}(T \times \text{TIME}))^2}{(k-1)(p-1)} + \frac{(\text{MS}(W))^2}{(N-k)(p-1)}}$$
- There is another way to deal with a repeated measure, consider “individual time point analysis.” This means

the data are analyzed separately at each time point, with an adjustment of α level. [9,10]

- An overlaid response-time plot is useful to visualize the trend of the PD response for between- and within-treatments comparisons.
- One major drawback for repeated-measures design is a higher possibility of encountering missing values. Four “imputation” procedures are commonly used:
 - Remove patients with missing values. This allows a straightforward statistical analysis. However, those incomplete patients may provide important information for the treatment.
 - Estimate the missing values by minimizing the sum of squares due to error. This is appropriate statistically only when very few missing values are observed in the study.
 - Replace the missing values with the last available observation. This is known as the “last observation carried forward” procedure, as suggested by Gillings and Koch. [11]
 - Replace the missing values with the mean of all valid observations.
- Two major sources of variation, as with the model in the section “Crossover Design Using a 2×2 Crossover Design,” are observed: inter-subject variation and intra-subject variation. In this model, the inter-subject variation contains the variation due to treatment and due to the patient within treatment; the intra-subject variation contains three components: time, treatment by time, and error. The mean square due to error is the estimate of intra-subject variance, and the mean square due to patient (within treatment) is the estimate of inter-subject variance.
- The model can be generalized to a higher-order analysis of variance/covariance (i.e., one or more “other explanatory variables”) with repeated measures.

Group 2

Simple Linear Regression

Study Design: Parallel group design.

Model Assumptions: Normal distribution, independence.

Number of Observations per Patient for PD Parameter: 1.

Purpose:

- To determine the relationship between a PD variable and a prespecified explanatory variable.
- To compare the relationship between the two treatment groups.

Within-Treatment-Group Analysis

Statistical Model: $y_{ij} = \alpha_i + \beta_i x_{ij} + \varepsilon_{ij}$ for $i = 1, 2, \dots, k; j = 1, 2, \dots, n_i$ where

- y_{ij} = PD value for patient j in treatment group i
- α_i = unknown intercept for treatment group i
- β_i = unknown slope for treatment group i
- x_{ij} = value of covariate for patient j in treatment group i
- ε_{ij} = random error associated with patient j in treatment group i

Point Estimation of Unknown Parameters for a Fixed i :

$$\hat{\beta}_i = \frac{S_{xy}^i}{S_{xx}^i}, \quad \hat{\alpha}_i = \bar{y}_i - \hat{\beta}_i \bar{x}_i, \quad \hat{y}_{ij} = \hat{\alpha}_i + \hat{\beta}_i x_{ij}$$

$$r_i = \frac{S_{xy}^i}{\sqrt{S_{xx}^i S_{yy}^i}}$$

where

$$S_{xy}^i = \sum_{j=1}^{n_i} (x_{ij} - \bar{x}_i)(y_{ij} - \bar{y}_i)$$

$$S_{xx}^i = \sum_{j=1}^{n_i} (x_{ij} - \bar{x}_i)^2 \text{ and } S_{yy}^i = \sum_{j=1}^{n_i} (y_{ij} - \bar{y}_i)^2$$

Hypothesis Testing for α_i : $H_0: \alpha_i = 0$ vs. $H_1: \alpha_i \neq 0$
Test Statistic:

$$T_0 = \frac{\hat{\alpha}_i}{\sqrt{\left(\frac{\sum_{j=1}^{n_i} (y_{ij} - \hat{y}_{ij})^2}{n_i - 2} \right) \left(\frac{1}{n_i} + \frac{\hat{x}_i^2}{S_{xx}^i} \right)}}$$

Rejection Region: $|T_0| > t_{(ni-2, 1-\alpha/2)}$
Two-Sided p Value: $2(1 - \text{PROBT}(|T_0|, n_i - 2))$
Hypothesis Testing for β_i : $H_0: \beta_i = 0$ vs. $H_1: \beta_i \neq 0$
Test Statistic:

$$T_0 = \frac{\hat{\beta}_i \sqrt{S_{xx}^i}}{\sqrt{\left(\frac{1}{n_i - 2} \sum_{j=1}^{n_i} (y_{ij} - \hat{y}_{ij})^2 \right)}}$$

Rejection Region: $|T_0| > t_{(ni-2, 1-\alpha/2)}$
Two-Sided p Value: $2(1 - \text{PROBT}(|T_0|, n_i - 2))$
Hypothesis Testing for ρ_i (Correlation Coefficient):
 $H_0: \rho_i = 0$ vs. $H_1: \rho_i \neq 0$

Test Statistic:

$$T_0 = \frac{r_i \sqrt{n_i - 2}}{\sqrt{1 - r_i^2}} \quad \text{for small } n_i (n_i < 20)$$

$$Z_0 = \frac{\frac{1}{2} \ln \frac{1 + r_i}{1 - r_i}}{\sqrt{\frac{1}{n_i - 3}}} \quad \text{for large } n_i (n_i \geq 20)$$

Rejection Region at α Level: $|T_0| > t_{(ni-2, 1-\alpha/2)}$ or $|Z_0| > Z_{(1-\alpha/2)}$

Two-Sided p Value:

$2(1 - \text{PROBT}(|T_0|, n_i - 2))$ or $2(1 - \text{PROBNORM}(|Z_0|))$

Analysis of Variance Approach (for Treatment Group i):

See Table 6.

Computation for Sum of Squares:

$$\text{SS}(X) = \frac{(S_{xy}^i)^2}{S_{xx}^i} \quad \text{and} \quad \text{SS}(E) = \sum_{j=1}^{n_i} (y_{ij} - \hat{y}_{ij})^2$$

Hypothesis Testing for No Relationship Between PD Parameter and Explanatory Variable: $H_0: \beta_i = 0$ vs.

$H_a: \beta_i \neq 0$

Test Statistic for No Relationship Between PD Parameter and Explanatory Variable: $F_0 = \text{MS}(X)/\text{MS}(E)$

Rejection Region at α Level: $F_0 > F_{(1, ni-2), 1-\alpha}$

Two-Sided p Value: $\text{PROBF}(F_0, 1, n_i - 2)$

Related SAS Procedure: PROC REG (or GLM).

Between-Treatment-Groups Analysis

Hypothesis Testing for $\rho_i - \rho_m$: $H_0: \rho_i = \rho_m$ vs. $H_a: \rho_i \neq \rho_m$

Test Statistic:

$$Z_0 = \frac{\frac{1}{2} \ln \frac{1 + r_i}{1 - r_i} - \frac{1}{2} \ln \frac{1 + r_m}{1 - r_m}}{\sqrt{\frac{1}{n_i - 3} + \frac{1}{n_m - 3}}}$$

Rejection Region: $|Z_0| > z_{(1-\alpha/2)}$

Two-Sided p Value: $2(1 - \text{PROBNORM}(|Z_0|))$

Hypothesis Testing for $\beta_i - \beta_m$: $H_0: \beta_i = \beta_m$ vs. $H_a: \beta_i \neq \beta_m$

Table 6 Analysis of Variance Summary for Treatment Group n_i

Source of variation	Degrees of freedom	Sum of squares	Mean squares
Regression	1	SS(X)	MS(X)
Error	$n_i - 2$	SS(E)	MS(E)
Corrected total	$n_i - 1$	SS(TOT)	

Test Statistic for $\beta_i - \beta_m$:

- a. For small sample size,

$$T_0 = \frac{\hat{\beta}_i - \hat{\beta}_m}{S_{\text{pool}} \sqrt{\frac{1}{S_{xx}^i} + \frac{1}{S_{xx}^m}}}$$

where

$$S_{\text{pool}}^2 = \frac{\sum_{j=1}^{n_i} (y_{ij} - \hat{y}_{ij})^2 + \sum_{j=1}^{n_m} (y_{mj} - \hat{y}_{mj})^2}{n_i + n_m - 4}$$

- b. For large sample size ($n_i > 25$ and $n_m > 25$),

$$Z_0 = \frac{\hat{\beta}_i - \hat{\beta}_m}{\sqrt{\frac{1}{n_i - 2} \sum_{j=1}^{n_i} (y_{ij} - \hat{y}_{ij})^2 \frac{1}{S_{xx}^i} + \frac{1}{n_m - 2} \sum_{j=1}^{n_m} (y_{mj} - \hat{y}_{mj})^2 \frac{1}{S_{xx}^m}}}$$

Rejection Region at α Level: $|T_0| > t_{(ni+nm-4, 1-\alpha/2)}$ or $|Z_0| > Z_{(1-\alpha/2)}$

Two-Sided p Value: $2(1 - \text{PROBT}(|T_0|, n_i + n_m - 4))$ or $2(1 - \text{PROBNORM}(|Z_0|))$

Description of and Notes on the Method:

- The explanatory variable for this model is specified as continuous. In fact, regression analysis will work fine with discrete explanatory variables in an ordinal scale with a reasonable number of different values
- The regression analysis focuses on the relationship between the identified explanatory variable and the PD parameter within the treatment group. That is different from an analysis of covariance (discussed in the next section), which focuses more on the between-treatments comparison. In addition, this regression model does not assume that all treatment groups have equal slope.
- It can be seen that there are two approaches to deal with within-treatment regression analysis. But both methods for testing a zero slope are the same (one using a t -test, the other using an F -test).
- There are two measures of interest with regard to the relationship between the PD parameter and the explanatory variable: one is measured as a linear slope, the other is expressed as a correlation coefficient.
- Confidence intervals for intercept and slope can be constructed.

- f. It is often desirable to obtain a confidence interval for the mean response at a fixed value (say, at x_0) of the explanatory variable for treatment group i , which is given by:

$$\bar{y}_i + \hat{\beta}_i(x_0 - \bar{x}_i) \pm t_{(n_i-2, 1-\alpha/2)} \times \sqrt{\left(\frac{\sum_{j=1}^n (y_{ij} - \hat{y}_{ij})^2}{n_i - 2} \right) \left(\frac{1}{n_i} + \frac{(x_0 - \bar{x}_i)^2}{S_{xx}^i} \right)}$$

- A regression plot with the predicted line is always made for this analysis. In addition, it is usually of great interest to construct confidence bands for the regression line.
- ρ_i = unknown population correlation coefficient for treatment group i and r_i = observed correlation coefficient for treatment group i .
- When only one explanatory variable is employed, we have a simple linear regression, which is discussed in this section.
- If more than one observation occurs for most of the values for the explanatory variable, the error term in the ANOVA can be partitioned into two components: pure error (PE) and lack of fit (LOF). $SS(\text{PE})$ can be calculated by summing up the sum of squares for all PDs at the same x value, and $d.f.(\text{PE}) = u$ (where u = number of different values of x). Thus, $SS(\text{LOF}) = SS(\text{Error}) - SS(\text{PE})$, and $d.f.(\text{LOF}) = d.f.(\text{Error}) - d.f.(\text{PE})$. In such a case, a test of the adequacy of the model can be made by means of the test statistic of the form $F = MS(\text{LOF})/MS(\text{PE})$. Note that the denominator of the test statistic for X remains unchanged [i.e., $MS(\text{Error})$].
- When more than one explanatory variable is employed, we have a multiple linear regression. The degrees of freedom (d.f.) for the source of "regression" in the ANOVA table are equal to the number of explanatory variables.
Associated with the multiple regression model are multiple correlation, partial correlation, overall F -test, and partial F -test. The details can be found in any statistics book that discusses the topic of multiple regression (e.g., Ref. [12]).
- In a simple regression case, a second-order or higher term may also be needed for the model, which is known as polynomial regression.^[12]
- A non-parametric method using ranks may be applied to regression analysis.^[13]
- Linearity is the simplest situation between the two variables; it is much more complicated when the relationship is nonlinear.^[14,15]

One-Way Analysis of Covariance

Study Design: Parallel group design.

Model Assumptions: Normal distribution, independence, equal variance, equal slope for all treatment groups.

Number of Observations for PD Parameter per Patient: 1.

Purpose: To compare the mean adjusted for covariate(s) of all treatment groups are equal.

Statistical Model: $y_{ij} = \alpha_i + \beta x_{ij} + \varepsilon_{ij} = \mu + \tau_i + \beta x_{ij}$ for $i = 1, 2, \dots, k; j = 1, 2, \dots, n_i$ where

- y_{ij} = PD value for patient j in treatment group i
- α_i = unknown intercept for treatment group i
- β = unknown common slope
- μ = overall population mean
- τ_i = treatment effect for treatment group i
- x_{ij} = value of the covariate for patient j in treatment group i
- ε_{ij} = random error associated with patient j in treatment group i

Analysis of Variance Summary: See Table 7.

Computation for Sum of Squares:

$$SS(\text{TOT}) = s_{yy}$$

$$SS(\text{E}) = \frac{\left(\sum_i S_{yy}^i \right) \left(\sum_i S_{xx}^i \right) - \left(\sum_i S_{xy}^i \right)^2}{\left(\sum_i S_{xx}^i \right)}$$

where

$$SS(\text{T}) = \frac{S_{yy}S_{xx} - S_{xy}^2}{S_{xx}} - SS(\text{E})$$

$$SS(\text{X}) = \left(\sum_i S_{yy}^i \right) - SS(\text{E})$$

Table 7 Analysis of Variance Summary for Parallel Group Design

Source of variation	Degrees of freedom	Sum of squares	Mean squares
Treatment	$k - 1$	$SS(\text{T})$	$MS(\text{T})$
Covariate	1	$SS(\text{X})$	$MS(\text{X})$
Error	$N - k - 1$	$SS(\text{E})$	$MS(\text{E})$
Corrected total	$N - 1$	$SS(\text{TOT})$	

$$S_{yy} = \sum_{i=1}^k \sum_{j=1}^{n_i} (y_{ij} - \bar{y}_{..})^2$$

$$S_{xx} = \sum_{i=1}^k \sum_{j=1}^{n_i} (x_{ij} - \bar{x}_{..})^2$$

$$S_{xy} = \sum_{i=1}^k \sum_{j=1}^{n_i} (x_{ij} - \bar{x}_{..})(y_{ij} - \bar{y}_{..})$$

$$S_{yy}^i = \sum_{j=1}^{n_i} (y_{ij} - \bar{y}_{i.})^2$$

$$S_{xx}^i = \sum_{j=1}^{n_i} (x_{ij} - \bar{x}_{i.})^2$$

$$S_{xy}^i = \sum_{j=1}^{n_i} (x_{ij} - \bar{x}_{i.})(y_{ij} - \bar{y}_{i.})$$

$$\bar{y}_{i.} = \sum_{j=1}^{n_i} y_{ij} / n_i$$

$$\bar{y}_{..} = \sum_{i=1}^k \sum_{j=1}^{n_i} y_{ij} / N$$

$$\bar{x}_{i.} = \sum_{j=1}^{n_i} x_{ij} / n_i, \quad \bar{x}_{..} = \sum_{i=1}^k \sum_{j=1}^{n_i} x_{ij} / N$$

$$N = \sum_{i=1}^k n_i$$

Point Estimation for the Unknown Parameters for a Fixed i :

$$\hat{\beta} = \frac{S_{xy}}{S_{xx}}, \quad \hat{\alpha}_i = \bar{y}_{i.} - \hat{\beta} \bar{x}_{i.}, \quad \hat{y}_{ij} = \hat{\alpha}_i + \hat{\beta} x_{ij}$$

Hypothesis Testing for Treatment Effect:

- $H_0: \tau_i = 0$ for all i , vs. $H_0: \tau_i \neq 0$ for some i if treatment effect is fixed.
- $H_0: \sigma_\tau^2 = 0$ vs. $H_a: \sigma_\tau^2 \neq 0$ if treatment effect is random.

Test Statistic for Treatment Effect: $F = MS(\text{T}) / MS(\text{E})$.

Rejection Region at α Level: $F > F_{(k-1, N-k-1), 1-\alpha}$.

Two-Sided p Value: $1 - \text{PROBF}_{(F_0, k-1, N-k-1)}$.

100(1 - α)% Confidence Interval for the Adjusted Mean Response for Treatment Group i :

$$\hat{\alpha}_i + \hat{\beta} \bar{x}_{i.} \pm t_{(N-k-1, 1-\alpha/2)} \sqrt{MS(\text{E}) \left(\frac{1}{n_i} + \frac{(\bar{x}_{i.} - \bar{x}_{..})^2}{S_{xx}} \right)}$$

100(1 - α)% Confidence Interval for the Difference of Adjusted Mean Response Between Treatment Group i and Treatment Group j :

$$\hat{\alpha}_i - \hat{\alpha}_j \pm t_{(N-k-1, 1-\alpha/2)} \sqrt{MS(E) \left(\frac{1}{n_i} + \frac{1}{n_j} \frac{(\bar{x}_i - \bar{x}_j)^2}{S_{xx}} \right)}$$

Hypothesis Testing for Slope: $H_0: \beta = 0$ vs. $H_0: \beta \neq 0$

Test Statistic for Slope: $F = MS(X)/MS(E)$.

Rejection Region at α Level: $F > F_{(1, N-k-1), 1-\alpha}$.

Two-Sided p Value: $1 - \text{PROBF}(F_0, 1, N-k-1)$.

Related SAS Procedure: PROC GLM (or MIXED).

Detailed Descriptions:

- When a covariate (an uncontrollable variable that is highly correlated with the PD parameter but not directly affected by the treatment) is taken into consideration in a clinical trial, analysis of covariance is a way to adjust for the covariate.
- This model can be extended to any number of covariates.
- Because a requirement for this model is the common slope among all treatment groups, a preliminary test on the common slope is recommended that can be done with the following model in SAS: $y_{ij} = \mu + \eta + \beta\eta + \varepsilon_{ij}$. The analysis of covariance is not appropriate if the interaction term of $\beta\tau_i$ is significant.
- Another way of handling a covariate in a situation where the covariate is the baseline is to adjust this value from the postdose PD value first and then to apply analysis of variance or other appropriate methods.
- The model is reduced to a linear regression if the treatment effect is insignificant. On the other hand, the model is reduced to a one-way analysis of variance if the slope associated with the covariate is insignificant.

Group 3

Cochran-Mantel-Haenszel Test

Study Design: Parallel group design.

Model Assumptions: Binomial distribution, independence.

Number of Observations per Patient for PD Parameter: 1.

Purpose: To compare the proportions of the two treatment groups based on stratified samples.

Hypothesis Testing: $H_0: \pi_1 = \pi_2$ vs. $H_a: \pi_1 \neq \pi_2$

Test Statistic:

$$M_0 = \frac{\left(\sum_i \left(n_{i11} - \frac{n_{i1+}n_{i1+}}{n_{i++}} \right) - 0.5 \right)^2}{\sum_i \left(\frac{n_{i1+}n_{i1+}n_{i2+}n_{i2+}}{n_{i++}^2(n_{i++} - 1)} \right)}$$

Table 8 Observed Frequencies for Group 3

Stratum I	Treatment 1	Treatment 2	Row total
Responder	n_{111}	n_{112}	n_{11+}
Non-responder	n_{121}	n_{122}	n_{12+}
Column total	n_{1+1}	n_{1+2}	n_{1++}

Rejection Region at α Level: $M_0 > \chi_{1, 1-\alpha}^2$

Two-Sided p Value: $1 - \text{PROBCHI}(M_0, 1)$.

Observed Frequency Table: See Table 8

Related SAS Procedure: PROC FREQ.

Description of and Notes on the Method:

- The stratum may represent study centers, gender, or patients' underlying condition (e.g., diabetics vs. non-diabetics), etc.
- The quantity "0.5" in the test statistics represents a correction for continuity, which may not be used.
- An interaction may exist if the difference of the two proportions varies from one stratum to another. Under this circumstance, each stratum shall be analyzed separately.
- The number of strata is best kept to a minimum, for at least two reasons:
 - To avoid small or empty cells.
 - Because the interaction term is difficult to interpret if significant.
- This test can be generalized to cases with k treatments ($k > 2$), r responses ($r > 2$), and s strata ($s > 2$).^[16] However, from a practical point of view, all k , r , and s shall be kept as small as possible for the same two reasons described in point (d).

Group 4

Logistic Regression

Study Design: Parallel group design.

Model Assumptions: Binomial distribution, independence.

Number of Observations per Patient for PD Parameter: 1.

Purpose: To determine the correlation between the proportion of the PD parameter and explanatory variable(s).

Statistical Model: $E \left(\log \left(\frac{\pi(x)}{1 - \pi(x)} \right) \right) = \alpha_0 + \sum_i \beta_i x_i$

Hypothesis Testing for One Correlation β_i : $H_0: \beta_i = 0$ vs. $H_1: \beta_i \neq 0$

Test Statistic for β_i : $\chi_w^2 = \left(\frac{\hat{\beta}_i}{SE(\hat{\beta}_i)} \right)^2$

Rejection Region for β_i at α level: $\chi_w^2 > \chi_{1, 1-\alpha/2}^2$.

Hypothesis Testing for a subset of model parameters β_q :

$H_0: \beta_q = 0$ vs. $H_a: \beta_q \neq 0$

Test Statistic for β_q : $\chi_w^2 = \mathbf{b}_q' (\text{COV}(\mathbf{b}_q))^{-1} \mathbf{b}_q$

Rejection Region for β_q at α level: $\chi_w^2 > \chi_q, 1 - \alpha/2^2$.

Related SAS Procedure: PROC LOGISTIC.

Description of and Notes on the Method:

- In this method, there are two responses for the PD parameter, with 0 indicating the non-occurrence of the event of interest, and 1 indicating non-non-occurrence.
- The notations in the model are defined as follows:
 - x_1 = treatment effect (if there are two treatments, such as active vs. control, we define $x_1=1$ for active drug and $x_1=0$ for placebo)
 - $x_2, \dots, x_k = k - 1$ other explanatory variables ($k \geq 1$), which can be continuous or discrete
 - $\pi(\mathbf{x})$ = probability of having event associated with $\mathbf{x} = (x_1, x_2, \dots, x_k)$
 - $E(Y)$ = expected value of Y
 - α_0 = intercept
 - β_i = unknown true correlation (slope) between $\pi(\mathbf{X})$ and x_i
 - $\beta_q = (\beta_1, \beta_2, \dots, \beta_q)'$ is a subset of $\beta = (\beta_1, \beta_2, \dots, \beta_k)'$, ($q \leq k$)
 - $\mathbf{b}_q = (b_1, b_2, \dots, b_q)'$ is an estimate of $\beta_q = (\beta_1, \beta_2, \dots, \beta_q)'$
 - $\text{COV}(\mathbf{b}_q)$ = variance-covariance matrix for $\mathbf{b}_q$,
 - $\text{SE}(\hat{\beta}_i)$ = standard error of $\hat{\beta}_i$
- The test statistic is called the Wald statistic, which is asymptotically chi square distributed with 1 degree of freedom for a sufficiently large sample size. The first test statistic is a special case of the second test statistic when $q=1$.
- There is another common test for logistic regression, which is well known as the maximum log-likelihood test, which is asymptotically chi square distributed with q d.f.
- We should first test β_i for any $i \geq 2$ to determine which covariates are correlated with the proportion of the PD response. Then we test β_1 for the proportion between the two treatment groups.

f. Note that
$$\pi(x) = \frac{1}{1 + \exp\left(-\left[\alpha_0 + \sum_i \beta_i x_i\right]\right)}$$

Hence, in the case of two treatments we have

$$x(x_1=1) = \frac{1}{1 + \exp\left(-\left[\alpha_0 + \sum_{i \geq 2} \beta_i x_i\right]\right)} \quad \text{and}$$

$$x(x_1=0) = \frac{1}{1 + \exp\left(-\left[\alpha_0 + \beta_1 \sum_{i \geq 2} \beta_i x_i\right]\right)}$$

- Again, in the case of two treatments, the odds for the control group is given by
